GROUND-WATER RESOURCES OF VAL VERDE COUNTY, TEXAS

By

R. D. Reeves and T. A. Small
United States Geological Survey

ABSTRACT

The principal water-bearing unit in Val Verde County is the Edwards and associated limestones. The Glen Rose Limestone, Boquillas Flags, and alluvium locally yield water to a few wells. Nearly all of the water used in the county is obtained from ground-water sources; however, the amount used is only a small fraction of the amount available for use.

A total of about 1,850 acre-feet or 1.7 mgd (million gallons per day) of water was pumped from wells in 1969. About 1,200 acre-feet (1.1 mgd) was used for rural-domestic supply and livestock, about 600 acre-feet (0.5 mgd) was used for irrigation, and 50 acre-feet (0.04 mgd) was used for municipal supply. A small but undetermined amount of water was pumped for industrial use. The city of Del Rio uses water from San Felipe Springs for its municipal supply; in 1969 the city used 6,780 acre-feet (6.0 mgd).

Additional large supplies of ground water are available for development. An average of about 500,000 acre-feet per year is discharged from the Edwards and

associated limestones through springs and seeps. The areas most favorable for the development of large-capacity wells are near the major streams, in areas of faults and fractures, and in the southern part of the county where a greater thickness of the Edwards is saturated.

Amistad Dam, which impounds water from the Rio Grande and Devils River northwest of Del Rio, was completed in 1968 as part of a multipurpose project by the United States and Mexico. After 1 year of impoundment, water levels in some wells tapping the Edwards and associated limestones near the lake rose more than 100 feet; water levels in wells farther removed from the lake rose progressively less.

The chemical quality of the ground water is generally suitable for public supply, industrial use, and irrigation; however, in the extreme southeastern part of the county, water from the Edwards and associated limestones contains high concentrations of magnesium and calcium sulfate and is too highly mineralized for most uses.

GROUND-WATER RESOURCES OF VAL VERDE COUNTY, TEXAS

INTRODUCTION

Purpose and Scope of the Investigation

The purpose of this investigation was to determine the occurrence, availability, dependability, and quality of ground water in Val Verde County.

The study, which was a cooperative project of the U.S. Geological Survey and the Texas Water Development Board, consisted of an inventory of all municipal, industrial, and irrigation wells and a large number of domestic-supply wells, livestock wells, observation wells (of the International Boundary and Water Commission), springs, and oil tests. Information was compiled on water use and pumpage and measurements of the depth to water in wells were made during the inventory. The surface geology was mapped so that the approximate recharge area of the Edwards and associated limestones could be delineated.

The well-data section of this report contains records of 526 wells and springs (Table 4), drillers' logs of 24 wells (Table 5), records of periodic water-level measurements in 55 wells (Table 6), and chemical analyses of 224 wells and springs (Table 7).

Location and Economic Development of the Area

Val Verde County is in southwest Texas on the southwestern edge of the Edwards Plateau (Figure 1). It covers 3,242 square miles and is the eighth largest county in areal extent in Texas. Del Rio, the county seat and principal commercial center, is 153 miles west of San Antonio and 426 miles east-southeast of El Paso.

In 1970, the population of Val Verde County was 26,984, of which 20,928 lived in Del Rio. The communities of Comstock, Langtry, Pumpville, Pandale, Juno, and Loma Alta have a combined population of approximately 1,000; the population of the county is static or very slowly increasing.

The production of wool and mohair is the predominant industry in the county. Hunting and fishing facilities constitute an important source of income in the county. Crop farming is confined to the stream valleys and is primarily for feed and grain, although some crops

are grown in the area around Del Rio. Del Rio is an important center for farm products and ranch supplies as well as a railroad, military, and tourist center.

Previous Investigations

Prior to this study, very little detailed information was available concerning the ground-water resources of Val Verde County. A report by Frazier (1940) contained records of wells and springs, drillers' logs, chemical analyses of water, and a map showing the well and spring locations; the well numbers used by Frazier and the corresponding numbers in this report are shown in Table 1.

Local investigations of ground-water conditions near Del Rio were made by Bennett (1942) and Bennett and Livingston (1942). Records of water levels in observation wells in Kinney, Uvalde, and Val Verde Counties were tabulated by Follett (1956).

The geology of a 3-mile-wide strip along the Rio Grande was mapped by the United States section of the International Boundary and Water Commission (1950-51) and published by the Bureau of Economic Geology of the University of Texas. The geology of part of the county has been mapped by Freeman (1964b, c, and 1965) and by Sharps and Freeman (1965).

Chemical analyses of water samples from wells and springs in southwestern Val Verde County and a potentiometric-surface map of the Edwards and associated limestones covering most of the county were prepared and published by the International Boundary and Water Commission, United States and Mexico (1956). A reconnaissance report on the ground-water resources of the middle Rio Grande Basin, including Val Verde County, was prepared by Brown and others (1965).

Selected unpublished well and spring data, water-level measurements, and chemical analyses from the files of the United States section of the International Boundary and Water Commission have been used in this report. The well numbers (ID or WO numbers) used by the Commission are given in the "remarks" column of the records of wells and springs (Table 4).

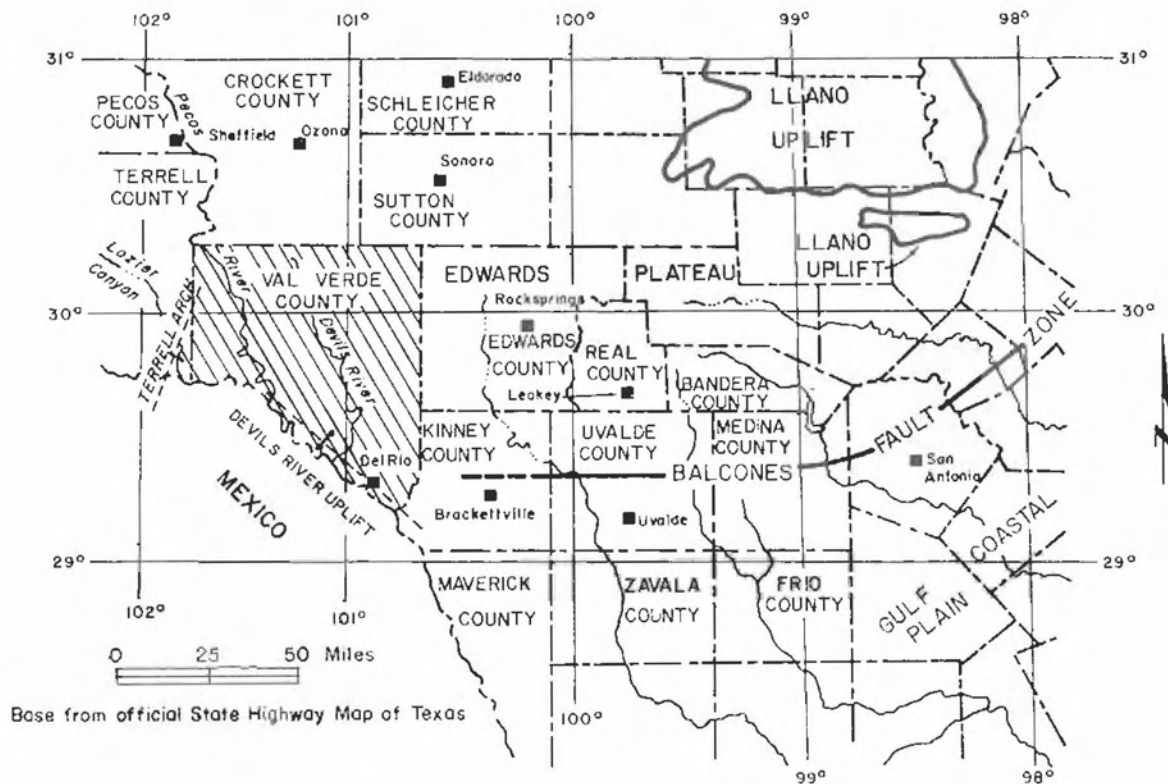

Figure 1.—Location of Val Verde County and Physiographic Features of Southwest-Central Texas

Well-Numbering System

The well-numbering system in this report, based on the divisions of latitude and longitude, is the one adopted by the Texas Water Development Board for use throughout the State. Figure 2 illustrates the well-numbering system. Under this system, each 1-degree quadrangle in the State is given a number consisting of two digits; the report area includes parts of quadrangles 54, 55, 70, and 71 (Figure 18). These are the first two digits appearing in the well number. Each 1-degree quadrangle is divided into 7½-minute quadrangles, which are given two-digit numbers from 01 to 64. These are the third and fourth digits of the well number. Each 7½-minute quadrangle is subdivided into 2½-minute quadrangles, which are given single-digit numbers from 1 to 9. This is the fifth digit of the well number. Finally, each well within a 2½-minute quadrangle is given a two-digit number, starting with 01. These are the last two digits of the well number. In addition to the seven-digit well number, a two-letter prefix is used to identify the county. The prefixes for Val Verde County and adjacent counties are as follows:

COUNTY	PREFIX	COUNTY	PREFIX
Crockett	HJ	Sutton	XS
Edwards	JJ	Terrell	XX
Kinney	RP	Val Verde	YR

Acknowledgments

Appreciation is expressed to the many landowners, ranchers, drillers, and city officials who supplied much of the information on which this report is based. A special note of thanks is due R. M. Price of the United States section of the International Boundary and Water Commission, who supplied a great deal of information about wells and springs in the southern part of the county; thanks also are due to the U.S. Commissioner, J. F. Friedkin, who gave permission to use much of the data collected by the United States section of the International Boundary and Water Commission.

Topography and Drainage

Most of the land surface of Val Verde County is predominantly rough and rolling terrain typical of the Edwards Plateau. The extreme southeastern part of the county consists of gentle, slightly rolling terrain characteristic of the Gulf Coastal Plain. Downcutting by the major streams in the southwestern and south-central parts of the county has formed fairly deep canyons with vertical to almost vertical walls. In the northern and western parts of the county, dissection of the plateau has created narrow valleys having steep slopes, except along the major streams where the valleys are much wider. The altitude of the land surface ranges from about 860 feet above mean sea level in the Rio Grande

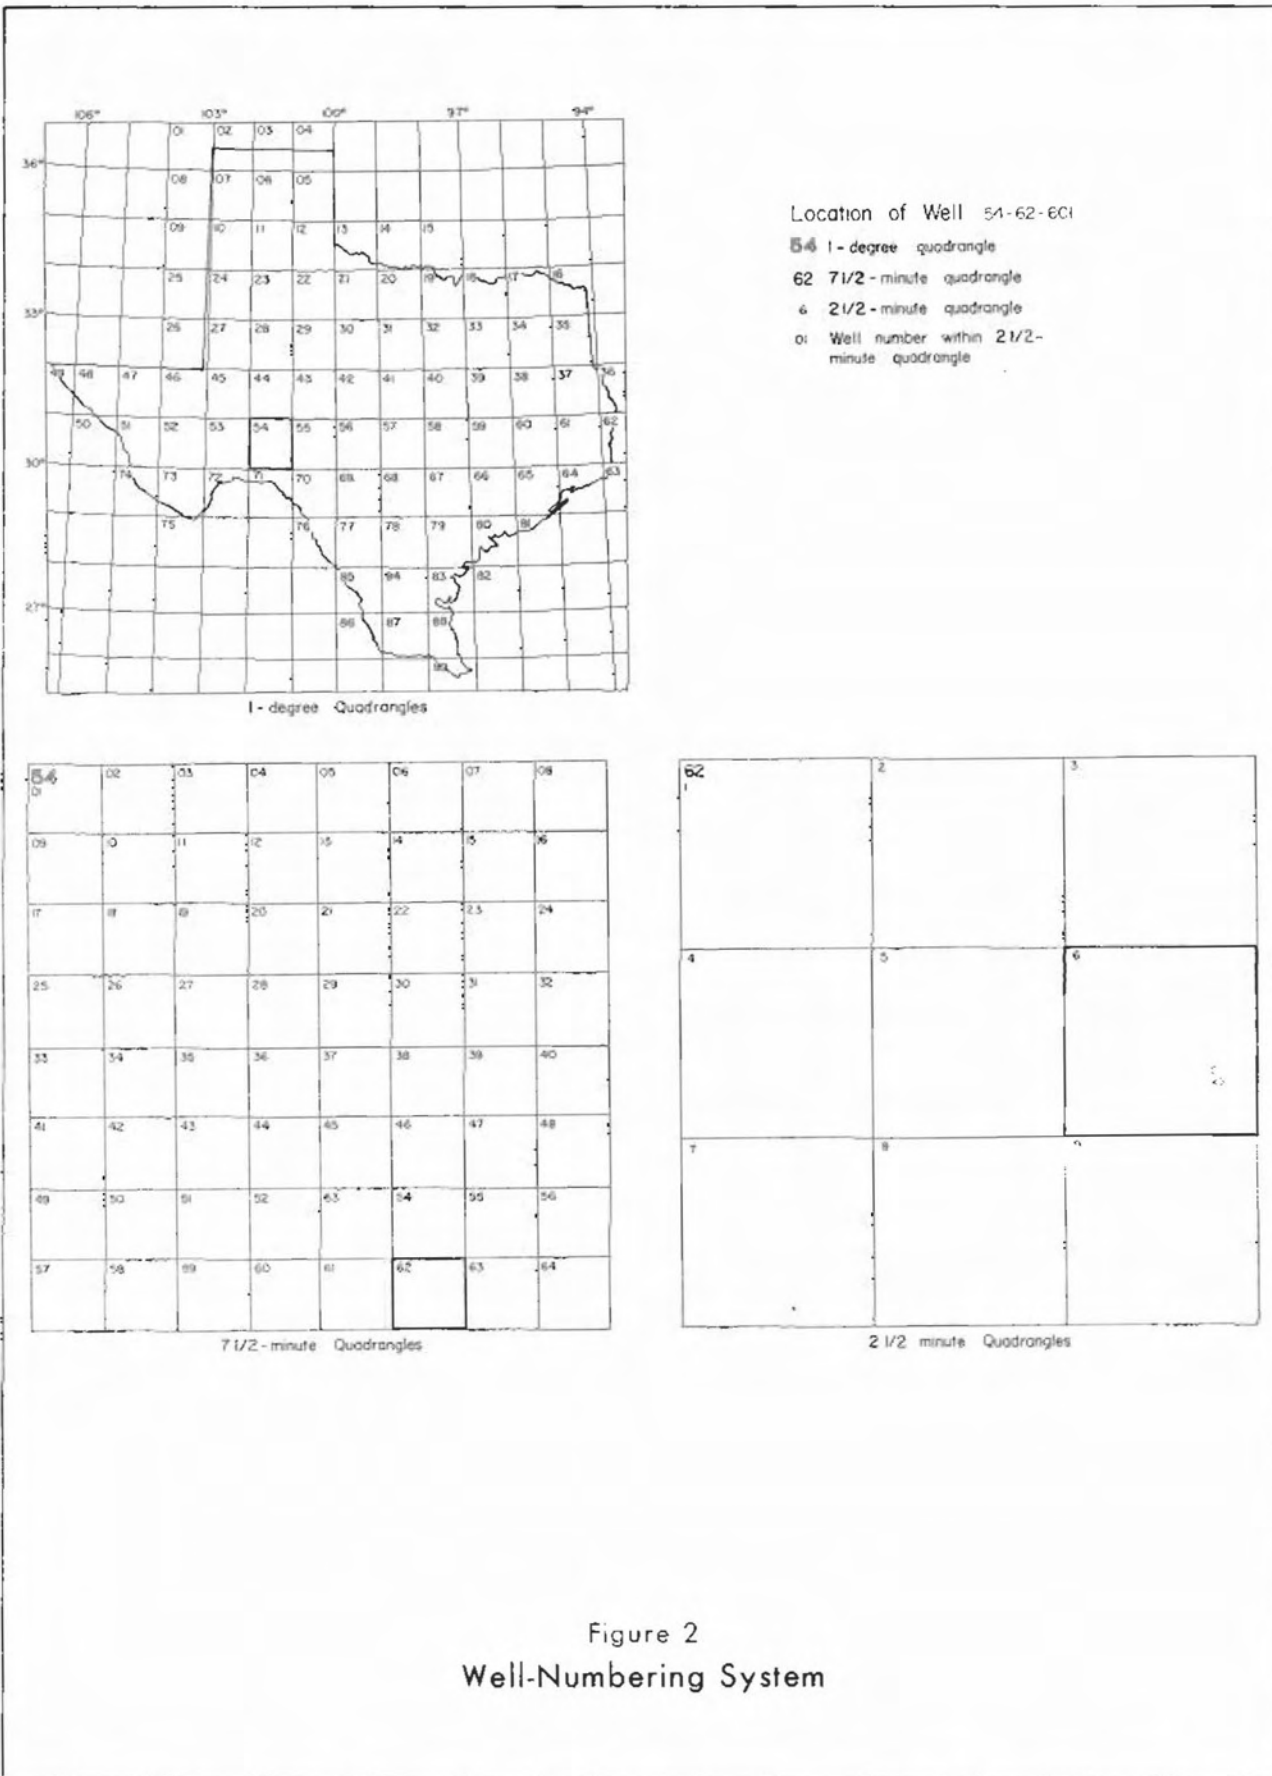

Figure 2
Well-Numbering System

valley in the southeastern part of the county to almost 2,400 feet in the northwestern part.

Val Verde County is drained by the Rio Grande, which forms the border between the United States and Mexico. The two principal tributaries to the Rio Grande in the county are the Pecos River, which enters the county in the northwest corner, and the Devils River, which originates in the north-central part of the county near Juno (Figure 18).

The U.S. Geological Survey and the International Boundary and Water Commission maintain a streamflow gaging station (08449000) on the Devils River near Juno. Records of streamflow at this station and miscellaneous measurements of streamflow at other points in the county are published each year by the U.S. Geological Survey in the annual series of "Water resources data for Texas, Part I: Surface water records."

The International Boundary and Water Commission has maintained 14 gaging stations within the county; records for eight of these stations and four discontinued stations are pertinent to this report. These stations are: Rio Grande at Foster's Ranch near Langtry (08377200); Pecos River near Shumla (08447400); Pecos River near Langtry (08447410); Pecos River at Mouth near Comstock (08447700); Goodenough Springs near Comstock (08448500); Devils River at Pafford Crossing near Comstock (08449400); Devils River at Mouth near Del Rio (08450500); Eight Mile Creek near Del Rio (08451130); McKee Spring near Del Rio (08451140); Cantu Spring on Cienegas Creek near Del Rio (08451300); Rio Grande near Del Rio (08452500); and San Felipe Spring at Del Rio (08452800). The locations of these stations are shown on Figure 18.

The records of streamflow and springflow at the stations maintained by the International Boundary and Water Commission are published each year by the Commission in the open-file bulletins "Flow of the Rio Grande and Related Data." Three of the stations, Pecos River at Mouth near Comstock, Goodenough Springs near Comstock, and Devils River at Mouth near Del Rio, were discontinued in 1968 because of inundation by Amistad Reservoir. The station Pecos River at Shumla was discontinued in 1967; the station Pecos River near Langtry was established 3 miles downstream from the discontinued station (Figure 18).

Climate

Val Verde County has a semiarid climate characterized by mild winters and hot summers. Average annual precipitation varies from about 22 inches in the eastern part of the county to about 12 inches in the western part. The average annual precipitation at Del Rio from 1931 through 1969 was 18.26 inches (Figure 3). Most of the rainfall occurs from April through October (Figure 4) chiefly as showers or heavy

downpours during thunderstorms. In general, the rainfall is insufficient for dry-land farming.

The average annual temperature at Del Rio is about 70°F (21°C). The average monthly temperature ranges from 52°F (11°C) in December and January to 85°F (29°C) in July and August (Figure 4). The average annual gross lake-surface evaporation from 1940 to 1965 was 86.0 inches (Kane, 1967), which is more than four times the average annual precipitation.

Average annual gross lake-surface evaporation at Amistad Dam for the period March 1963 through December 1967 was 115.29 inches, over seven times the average annual precipitation of 15.76 inches at the dam (International Boundary and Water Commission, United States and Mexico, 1967, p. 164).

GEOLOGY AS RELATED TO THE OCCURRENCE OF GROUND WATER

The geologic formations penetrated by water wells in Val Verde County are composed chiefly of limestones and dolomites that range in age from Early Cretaceous to Holocene. The geologic map (Figure 5) shows that the Edwards and associated limestones are exposed in approximately two-thirds of Val Verde County. These units dip to the south and southwest, and in most places in the southern and western parts of the county they are covered by younger formations. The Glen Rose Limestone is exposed in the extreme northwestern part of the county where the Pecos River has cut through the Edwards and associated limestones.

The primary structural feature affecting the occurrence of ground water is the dip of the rock units toward the south and southwest at 40 to 70 feet per mile (Figures 6, 7). Ground water, much of which enters the county as underflow from adjacent counties north and east of Val Verde County, moves down dip toward areas of discharge in the southern part of the county.

Small normal faults, or tension faults, and joints are common in the southern part of the county. Uplift during Pleistocene time probably preferentially "opened" the northeast-trending planes of weakness (fractures and bedding planes) in the rocks (Freeman, 1968, p. K21), and subsequent downward percolation of rainfall has enlarged the openings by solution resulting in a system of interconnected cavities.

The occurrence and movement of ground water is strongly controlled by these openings in the limestone and dolomite units. The depths at which these solution-widened bedding planes or fractures may be encountered by a well bore can vary widely within a short distance. Many of the springs in the county issue from northeast-trending faults and joints.

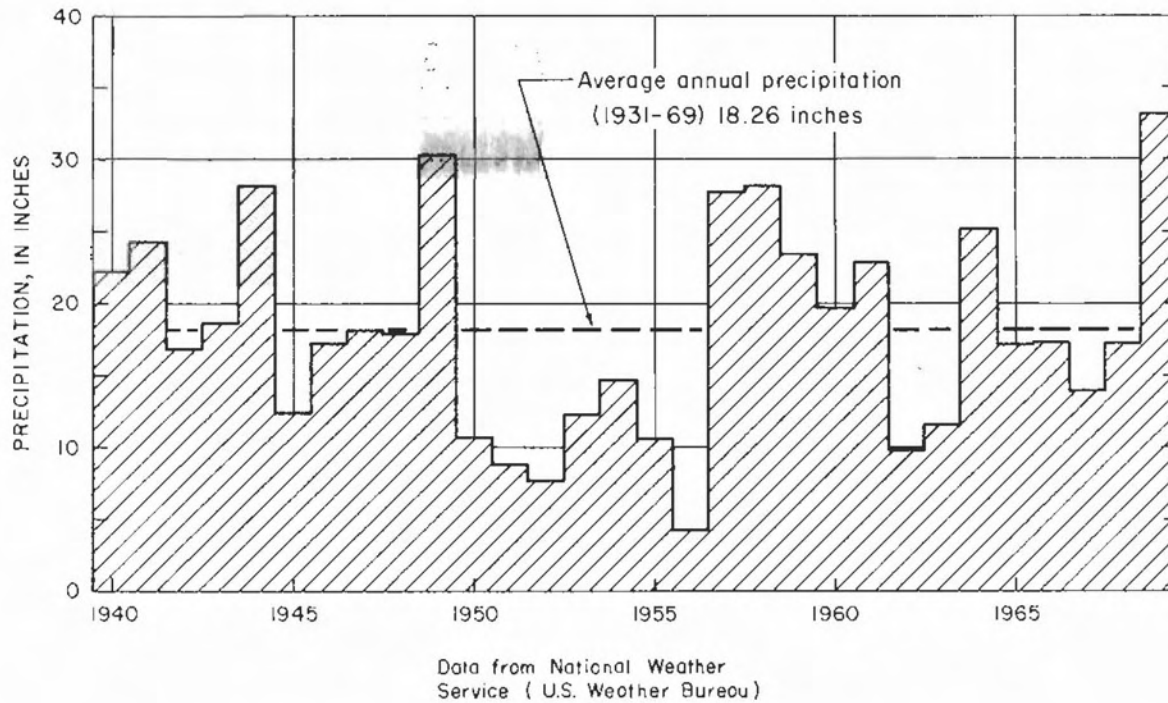

Figure 3.—Average Annual Precipitation at Del Rio

Data from National Weather Service (U.S. Weather Bureau)

Figure 4.—Average Monthly Temperature and Precipitation at Del Rio

The principal water-bearing unit in Val Verde County is the Edwards and associated limestones. A few wells locally obtain small quantities of water from the Glen Rose Limestone, the Boquillas Flags, and the alluvial deposits of Pleistocene and Holocene age. The lithology and water-bearing properties of all the units in the county are summarized in Table 2.

For general discussions of the relative well or spring yields, the following ratings are used:

DESCRIPTION	YIELD (GALLONS PER MINUTE)
Very small	0-5
Small	5-25
Moderate	25-100
Large	More than 100

Pre-Cretaceous Rocks

Pre-Cretaceous rocks are not exposed in Val Verde County. The nearest exposure is approximately 6 miles north, in Terrell and Crockett Counties, where a small area of Lower Permian limestone is exposed in the Pecos River Valley (West Texas Geological Society Guidebook, 1959, p. 54).

Table 2.—Stratigraphic Units and Their Water-Bearing Properties

SYSTEM	SERIES OR GROUP	STRATIGRAPHIC UNIT	APPROXIMATE MAXIMUM THICKNESS (FT)	CHARACTER OF ROCKS	WATER-BEARING PROPERTIES		
Quaternary	Pleistocene and Holocene	Alluvium	50	Clay, silt, sand, and gravel	Yields very small to moderate quantities of fresh water to a few domestic and livestock wells along the major streams.		
Cretaceous	Gulf Series	Austin Chalk	200	Thin- to thick-bedded limestones and thin beds shaly limestone.	Not known to yield water to wells in Val Verde County.		
		Boquillas Flags	258 +	Thin- to medium-bedded sandy limestone and thin beds of black calcareous shale.	Yields very small quantities of fresh to slightly saline water to a few livestock wells.		
	Comanche Series	Washita Group	Buda Limestone	90	Hard, porcelaneous and marly limestones.	Yields very small quantities of fresh water to a few domestic and livestock wells in Val Verde and Kinney Counties.	
			Del Rio	136 +	Shale and thin beds of arenaceous limestone and sandstone.	Not known to yield water to wells.	
		Edwards and associated limestones	Georgetown Limestone	500 +	Hard, massive limestone with thin stringers of shale; contains chert nodules and pyrite.	One of the principal aquifers in the county. Yields very small to large quantities of fresh water to livestock, domestic, irrigation, industrial and public supply wells in the southern part of the county.	
			Fredericksburg Group	Kiamichi Formation	283	Shaly limestone, calcareous shale, chert, and gypsum.	Generally yields small quantities of slightly to moderately saline water in the southern part of the county. Fresh water may be obtained from wells near the up-dip limit of the formation.
				Edwards Limestone	300	Hard, massive, cherty limestone and some dolomite.	One of the principal aquifers in the county. Yields very small to large quantities of fresh water to livestock, domestic, and irrigation wells in most of the county.
		Trinity Group	Comanche Peak Limestone	100	Marly, nodular limestone.	Not differentiated from Edwards Limestone.	
			Glen Rose Limestone	1,320	Shale, shaly limestone, limestone, and sand.	Yields very small to moderate quantities of water to livestock and domestic wells; much of the water is slightly saline.	
			Basement sand	445	Sand, sandstone, shale, shaly limestone, and dolomite.	Not known to yield water to wells in Val Verde County.	
Pre-Cretaceous	?	?	?	Limestone, shale, sandstone, dolomite, and volcanic and metamorphic rocks.	Except for one well, this unit is not a source of ground water in Val Verde County. In general, the pre-Cretaceous rocks probably contain water too highly mineralized for most uses.		

Cretaceous rocks are underlain by Lower Permian rocks in the northern and central parts of the county. In the southern part of the county the Cretaceous rocks are underlain by unmetamorphosed to highly metamorphosed lower Paleozoic rocks or by metamorphosed Precambrian rocks of the Devils River Uplift (Figure 1) (Flawn and others, 1961, p. 144). Drillers' logs of oil tests indicate that the pre-Cretaceous rocks in the northern and central parts of the county consist of shale, shaly sandstone, sandstone, limestone, and dolomite. The rocks in the southern part of the county consist of limestone, dolomite, shale, sandstone, volcanic rocks, and metamorphosed rocks such as marble, phyllite, slate, and quartzite.

Little is known of the water-bearing properties of the pre-Cretaceous rocks in Val Verde County. Water collected during a drill-stem test from a cavity in the Ellenburger Group at 2,408 feet in well YR-70-25-602 reportedly contained 200 mg/l (milligrams per liter) of chloride. Prior to the drill-stem test and after circulation had been lost in the cavity, the reported water level in the well was 332 feet below land surface. A water sample collected from the same well at approximately 5,650 feet reportedly contained 47,900 mg/l of chloride.

Not enough deep wells have been drilled in Val Verde County to determine the water-bearing properties of the pre-Cretaceous rocks. In general, the pre-Cretaceous rocks probably contain water that is too highly mineralized for most uses.

Cretaceous System

The lowermost Cretaceous rocks penetrated in oil tests in Val Verde County are referred to in this report as basement sands. Correlation is difficult, but the unit probably includes in part the Hosston and Sligo Formations of Coahuila age and the Pearsall Formation of Comanche age (Imlay, 1945, p. 1425-41). The basement sands do not crop out in Val Verde County. The approximate altitude of the base of the Cretaceous rocks is shown in Figure 6.

According to logs of several oil tests, the basement sands are composed chiefly of sand, sandstone, shale, shaly limestone, and dolomite. Thickness of the unit is variable but is generally less than 50 feet in most of the county (Figures 8 and 9). The maximum reported thickness is 445 feet in well YR-70-41-207. The unit may be absent in places on the structural high in the southern part of the county (Figure 10).

Not enough deep wells have been drilled to determine the water-bearing properties of the unit. Nevertheless, it is likely that the water available in the basement sands would be too highly mineralized for most uses.

Trinity Group

Glen Rose Limestone

The Glen Rose Limestone, the oldest formation exposed in Val Verde County, crops out along the Pecos River in the extreme northwestern part of the county (Figure 5).

The Glen Rose Limestone consists chiefly of shale, shaly limestone, and thin-bedded limestone in the upper part, with thicker, more massive beds of limestone in the lower part. The Glen Rose ranges in thickness from about 1,320 feet in the southern part of the county to about 380 feet in the northern part (Figure 8).

The Glen Rose Limestone yields very small to moderate quantities of mostly slightly saline water (1,000 to 3,000 mg/l of dissolved solids) to a few wells in the northern part of the county. Generally, this water is too mineralized for domestic use, but it is satisfactory for livestock.

Fredericksburg and Washita Groups

The Fredericksburg Group in Val Verde County includes, in ascending order, the Comanche Peak Limestone, the Edwards Limestone, and the Kiamichi Formation. The Walnut Clay, the lowermost formation of the Fredericksburg Group, has not been recognized in Val Verde County. The Washita Group includes the Georgetown Limestone, the Del Rio Clay, and the Buda Limestone. The Comanche Peak Limestone, the Edwards Limestone, the Kiamichi Formation (where present), and the Georgetown Limestone form a single hydrologic unit and are referred to as the Edwards and associated limestones. The approximate altitude of the base of the Fredericksburg Group is shown on Figure 7.

Comanche Peak Limestone

The Comanche Peak Limestone, the oldest formation in the Fredericksburg Group, crops out along the Pecos River in the extreme northwestern part of the county.

The Comanche Peak consists of a light-gray, marly, nodular limestone ranging in thickness from 100 feet in the subsurface to 20 feet at the outcrop.

Although the Comanche Peak Limestone is recognizable at the outcrop, it is difficult to distinguish between the Comanche Peak and the Edwards and associated limestones in drill cutting and on electric logs; consequently, the water-bearing properties of the Comanche Peak are not known, and the formation is included as part of the Edwards and associated limestones.

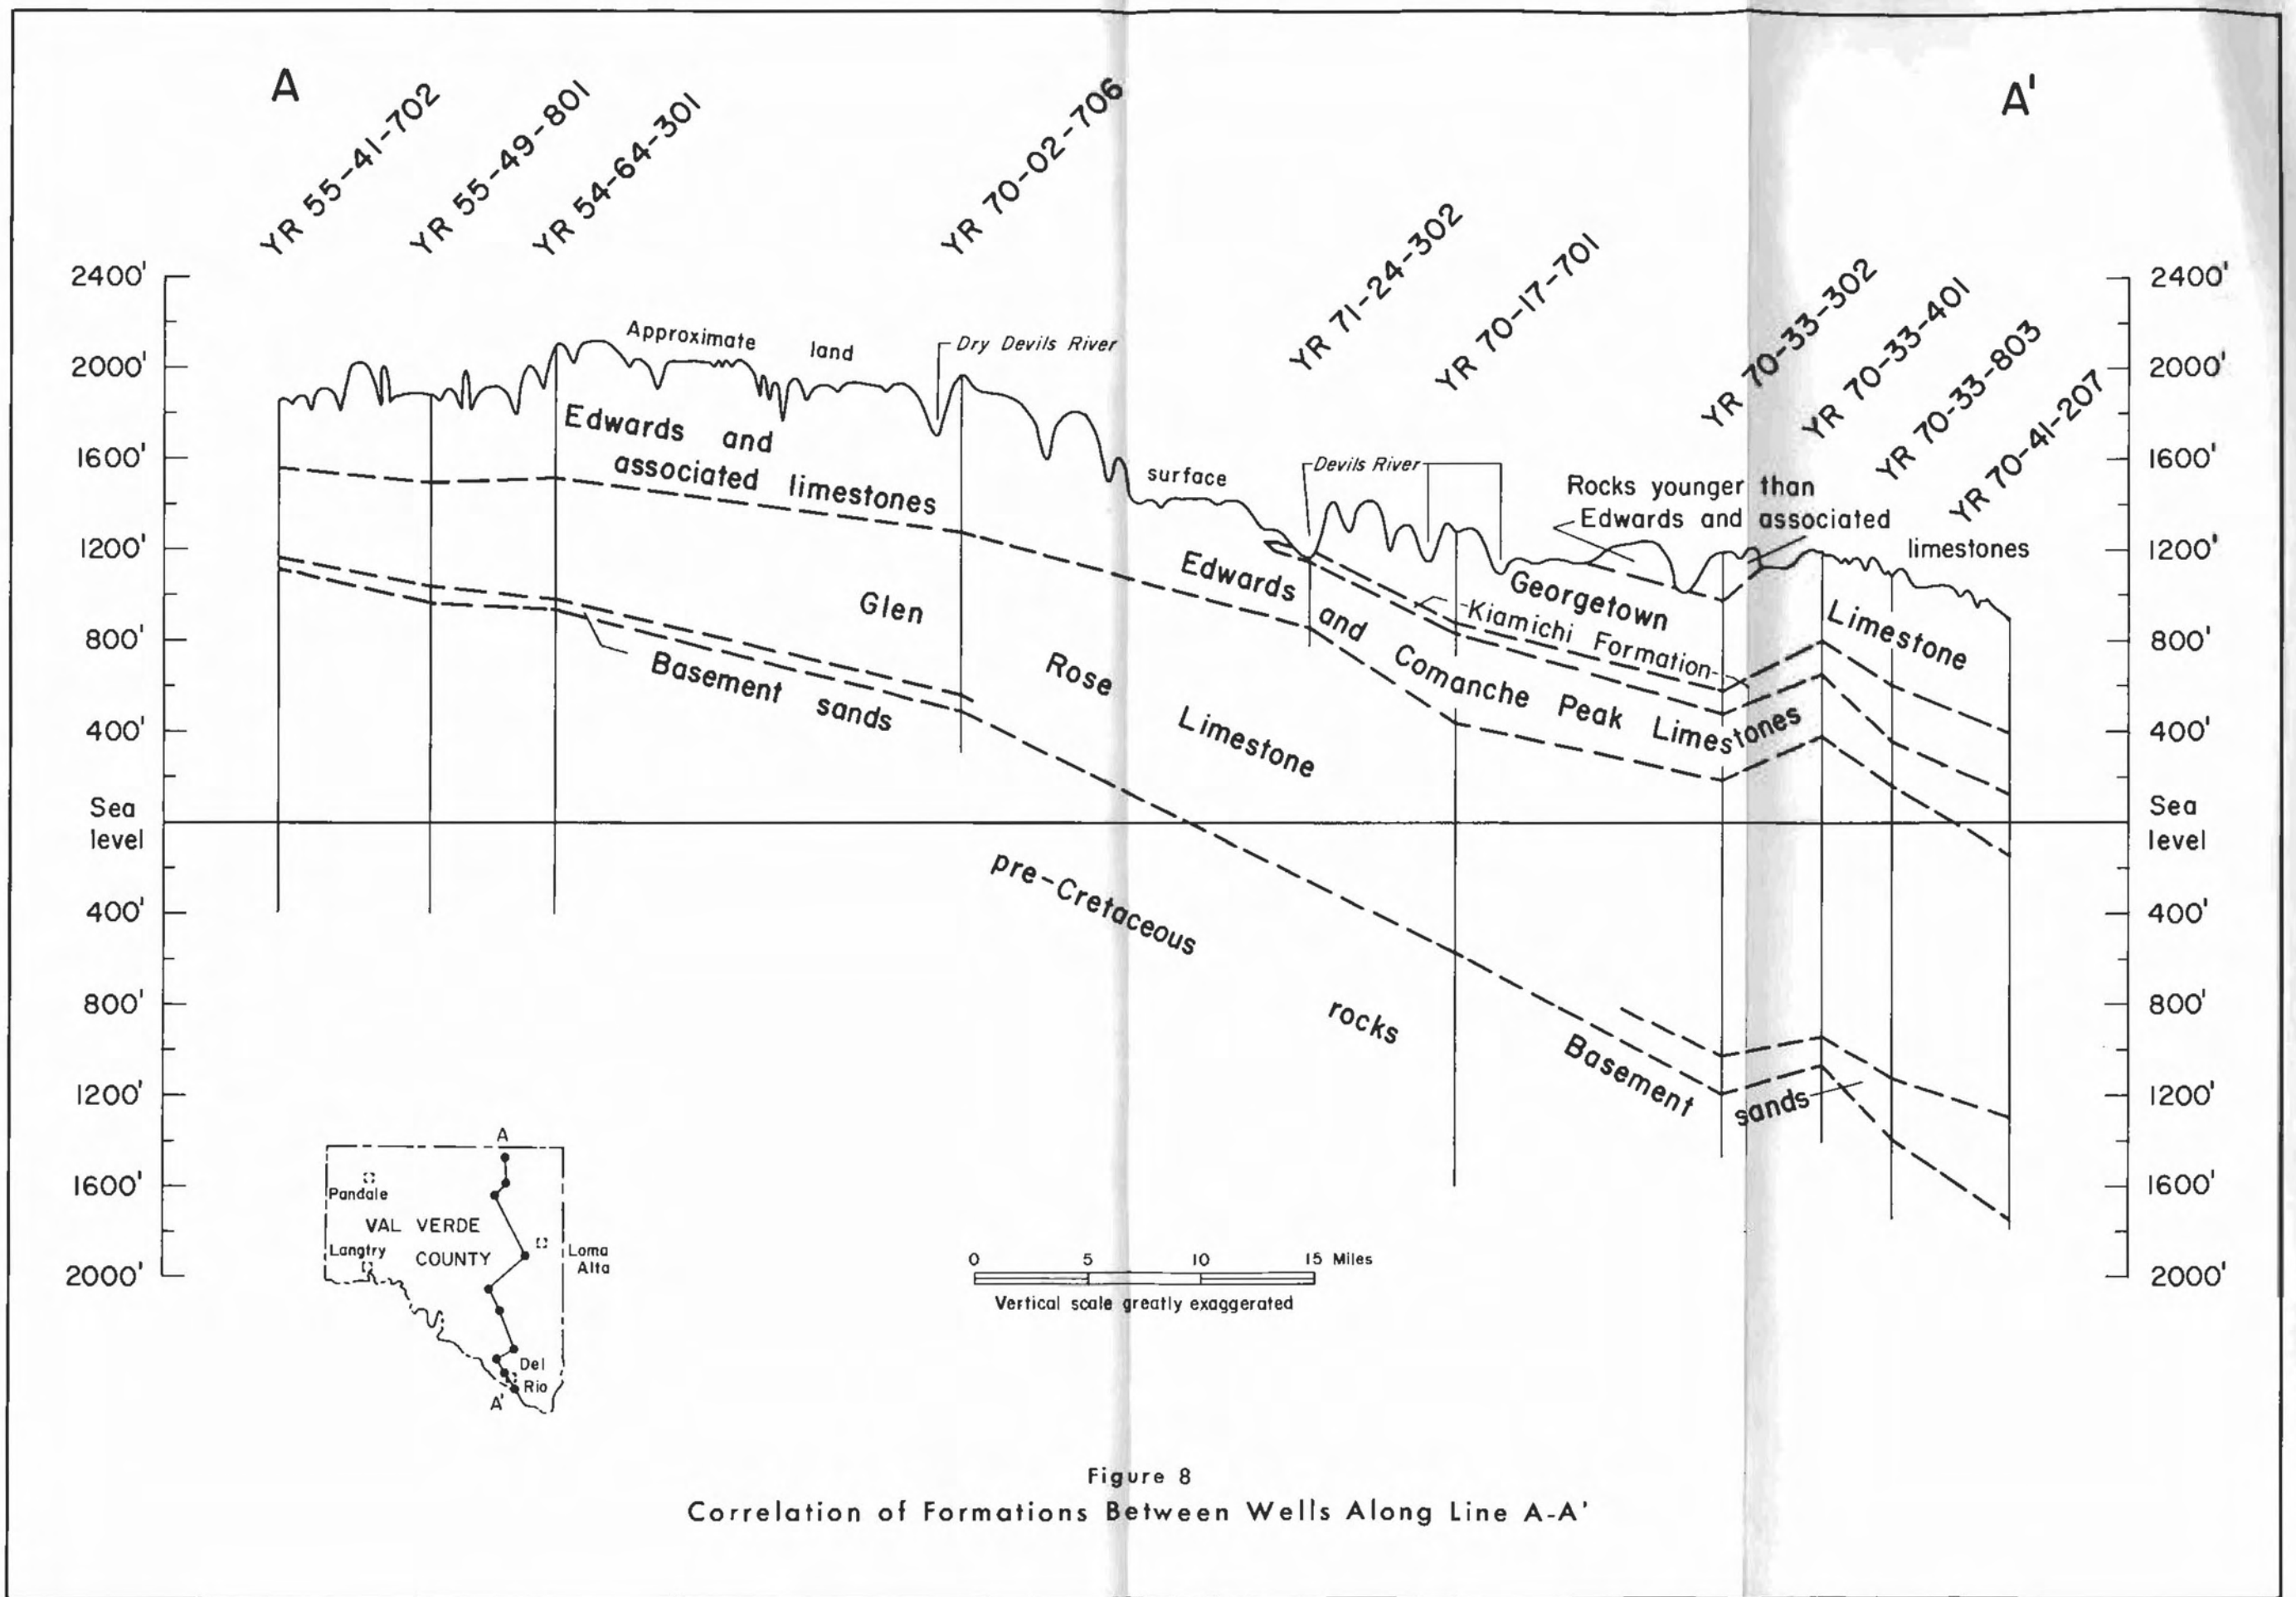

Figure 8
Correlation of Formations Between Wells Along Line A-A'

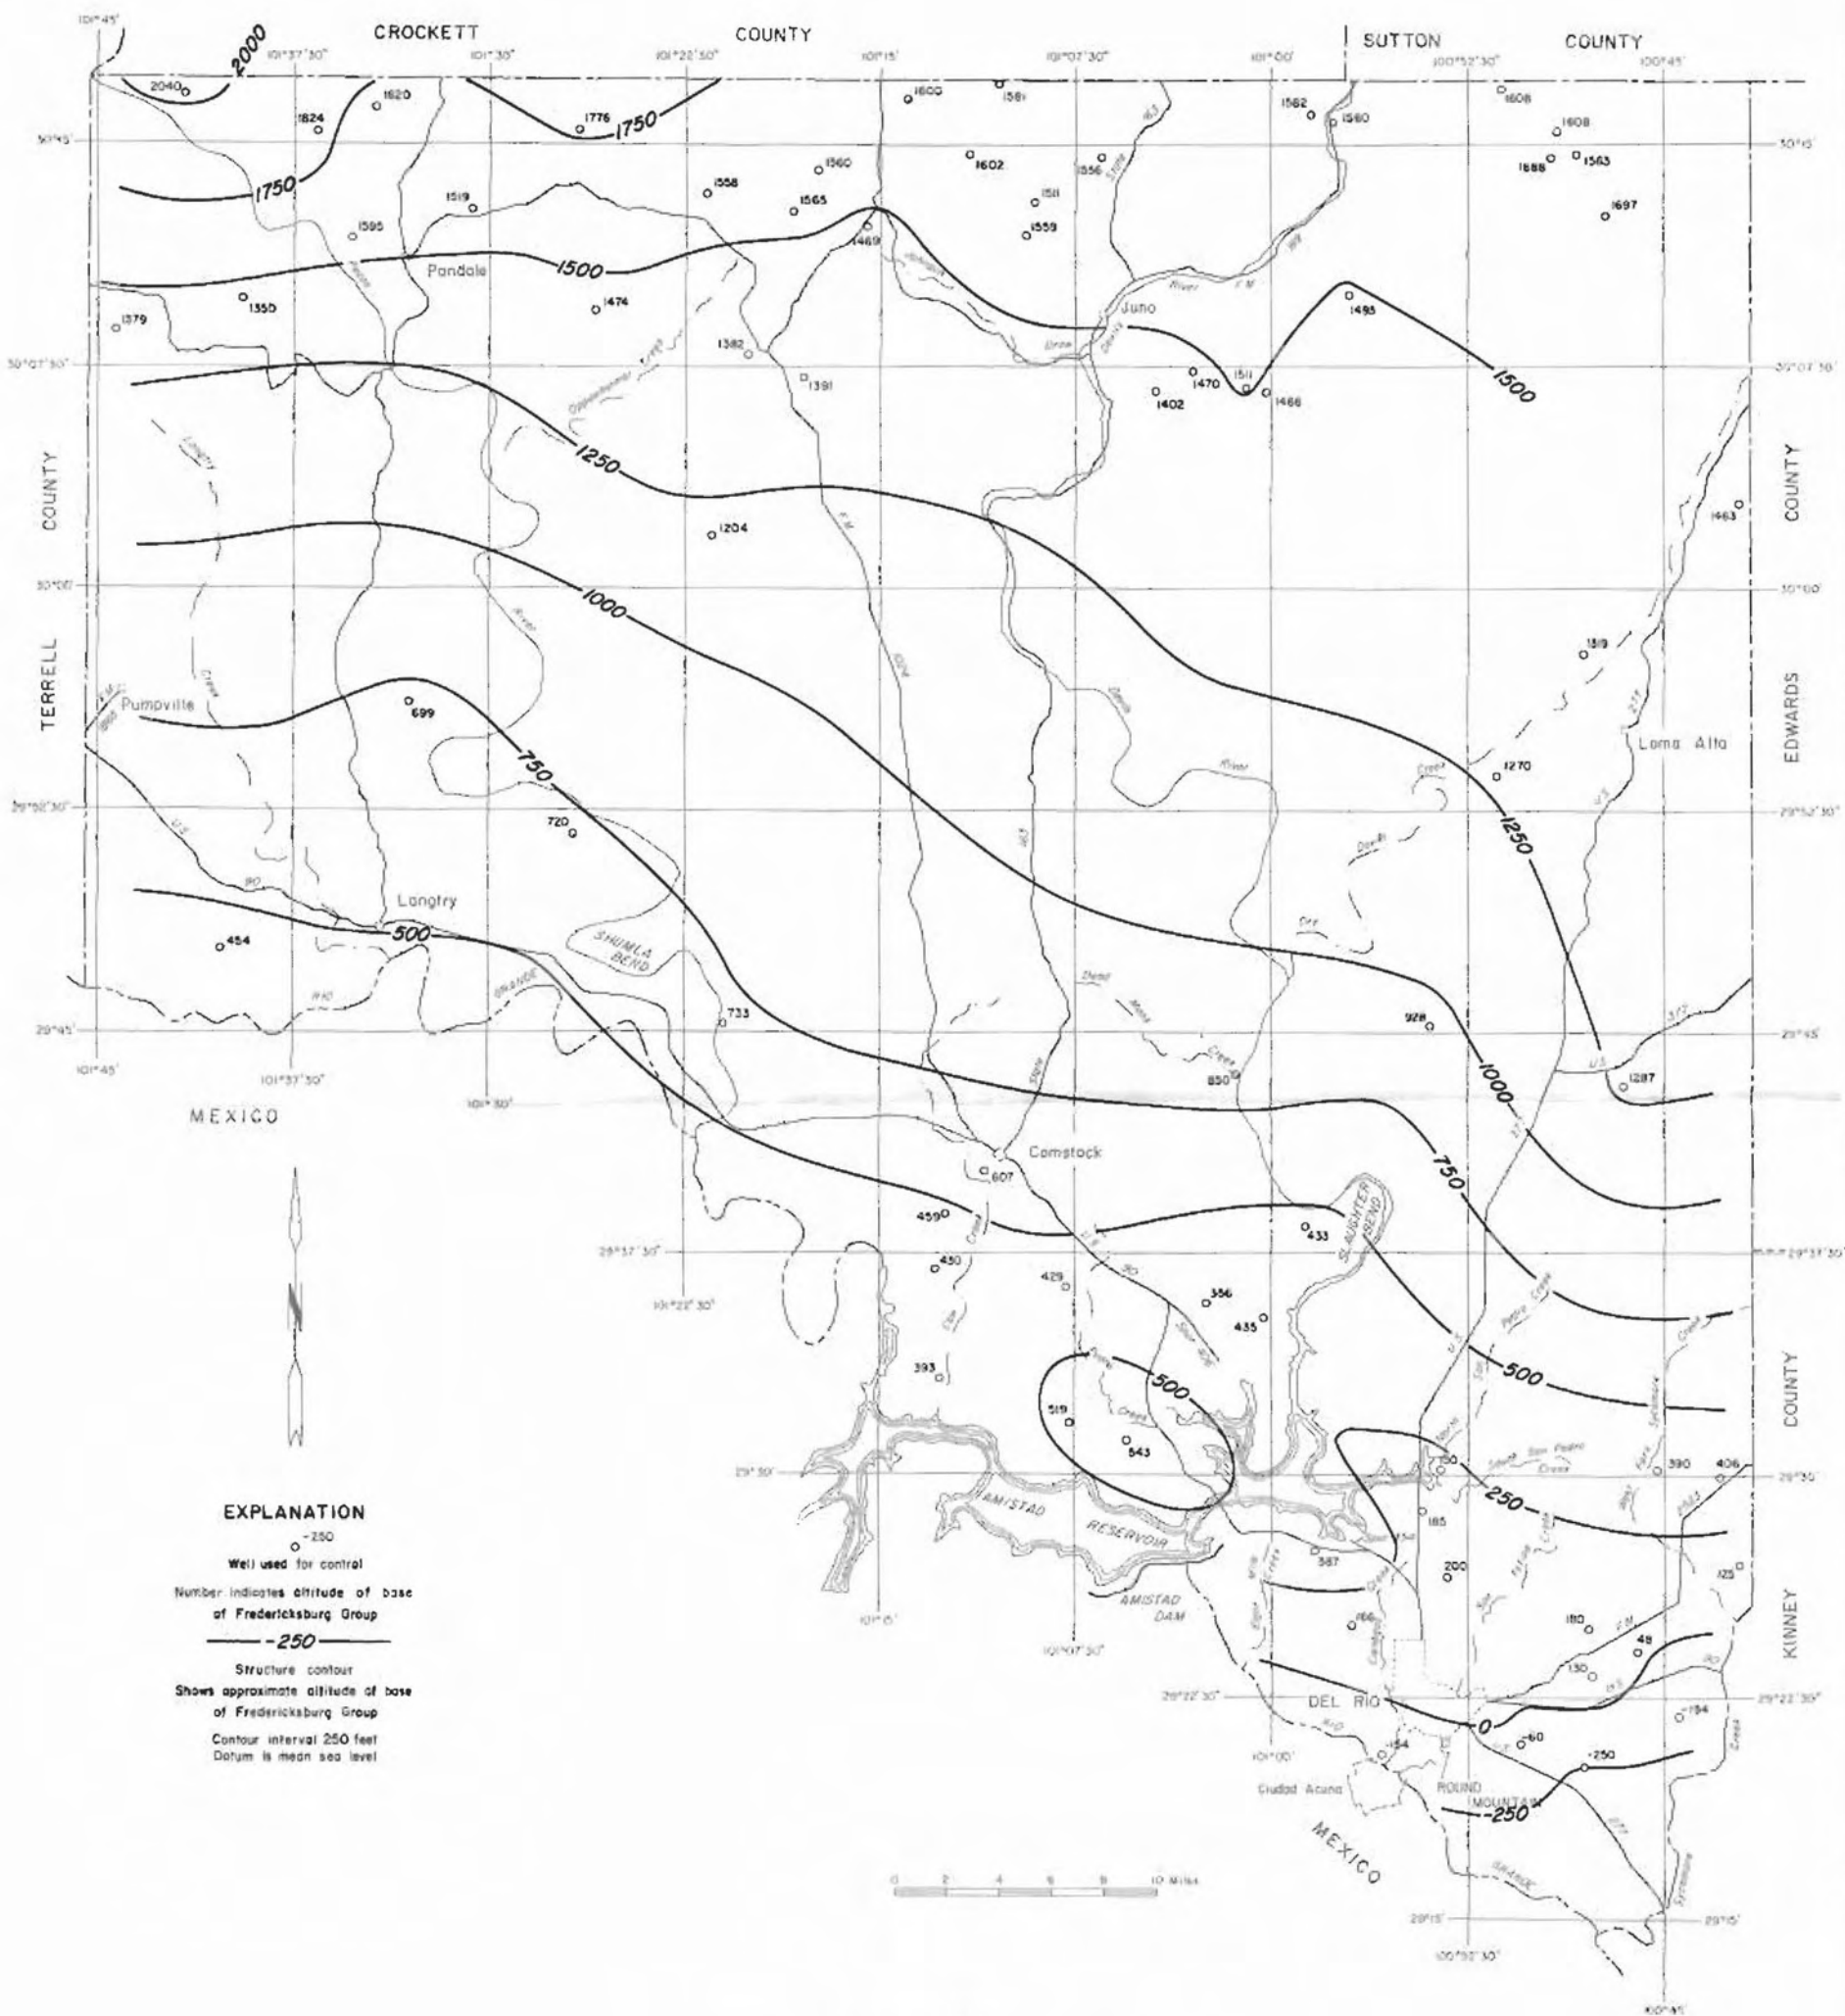

Figure 7

Approximate Altitude of the Base of the Fredericksburg Group

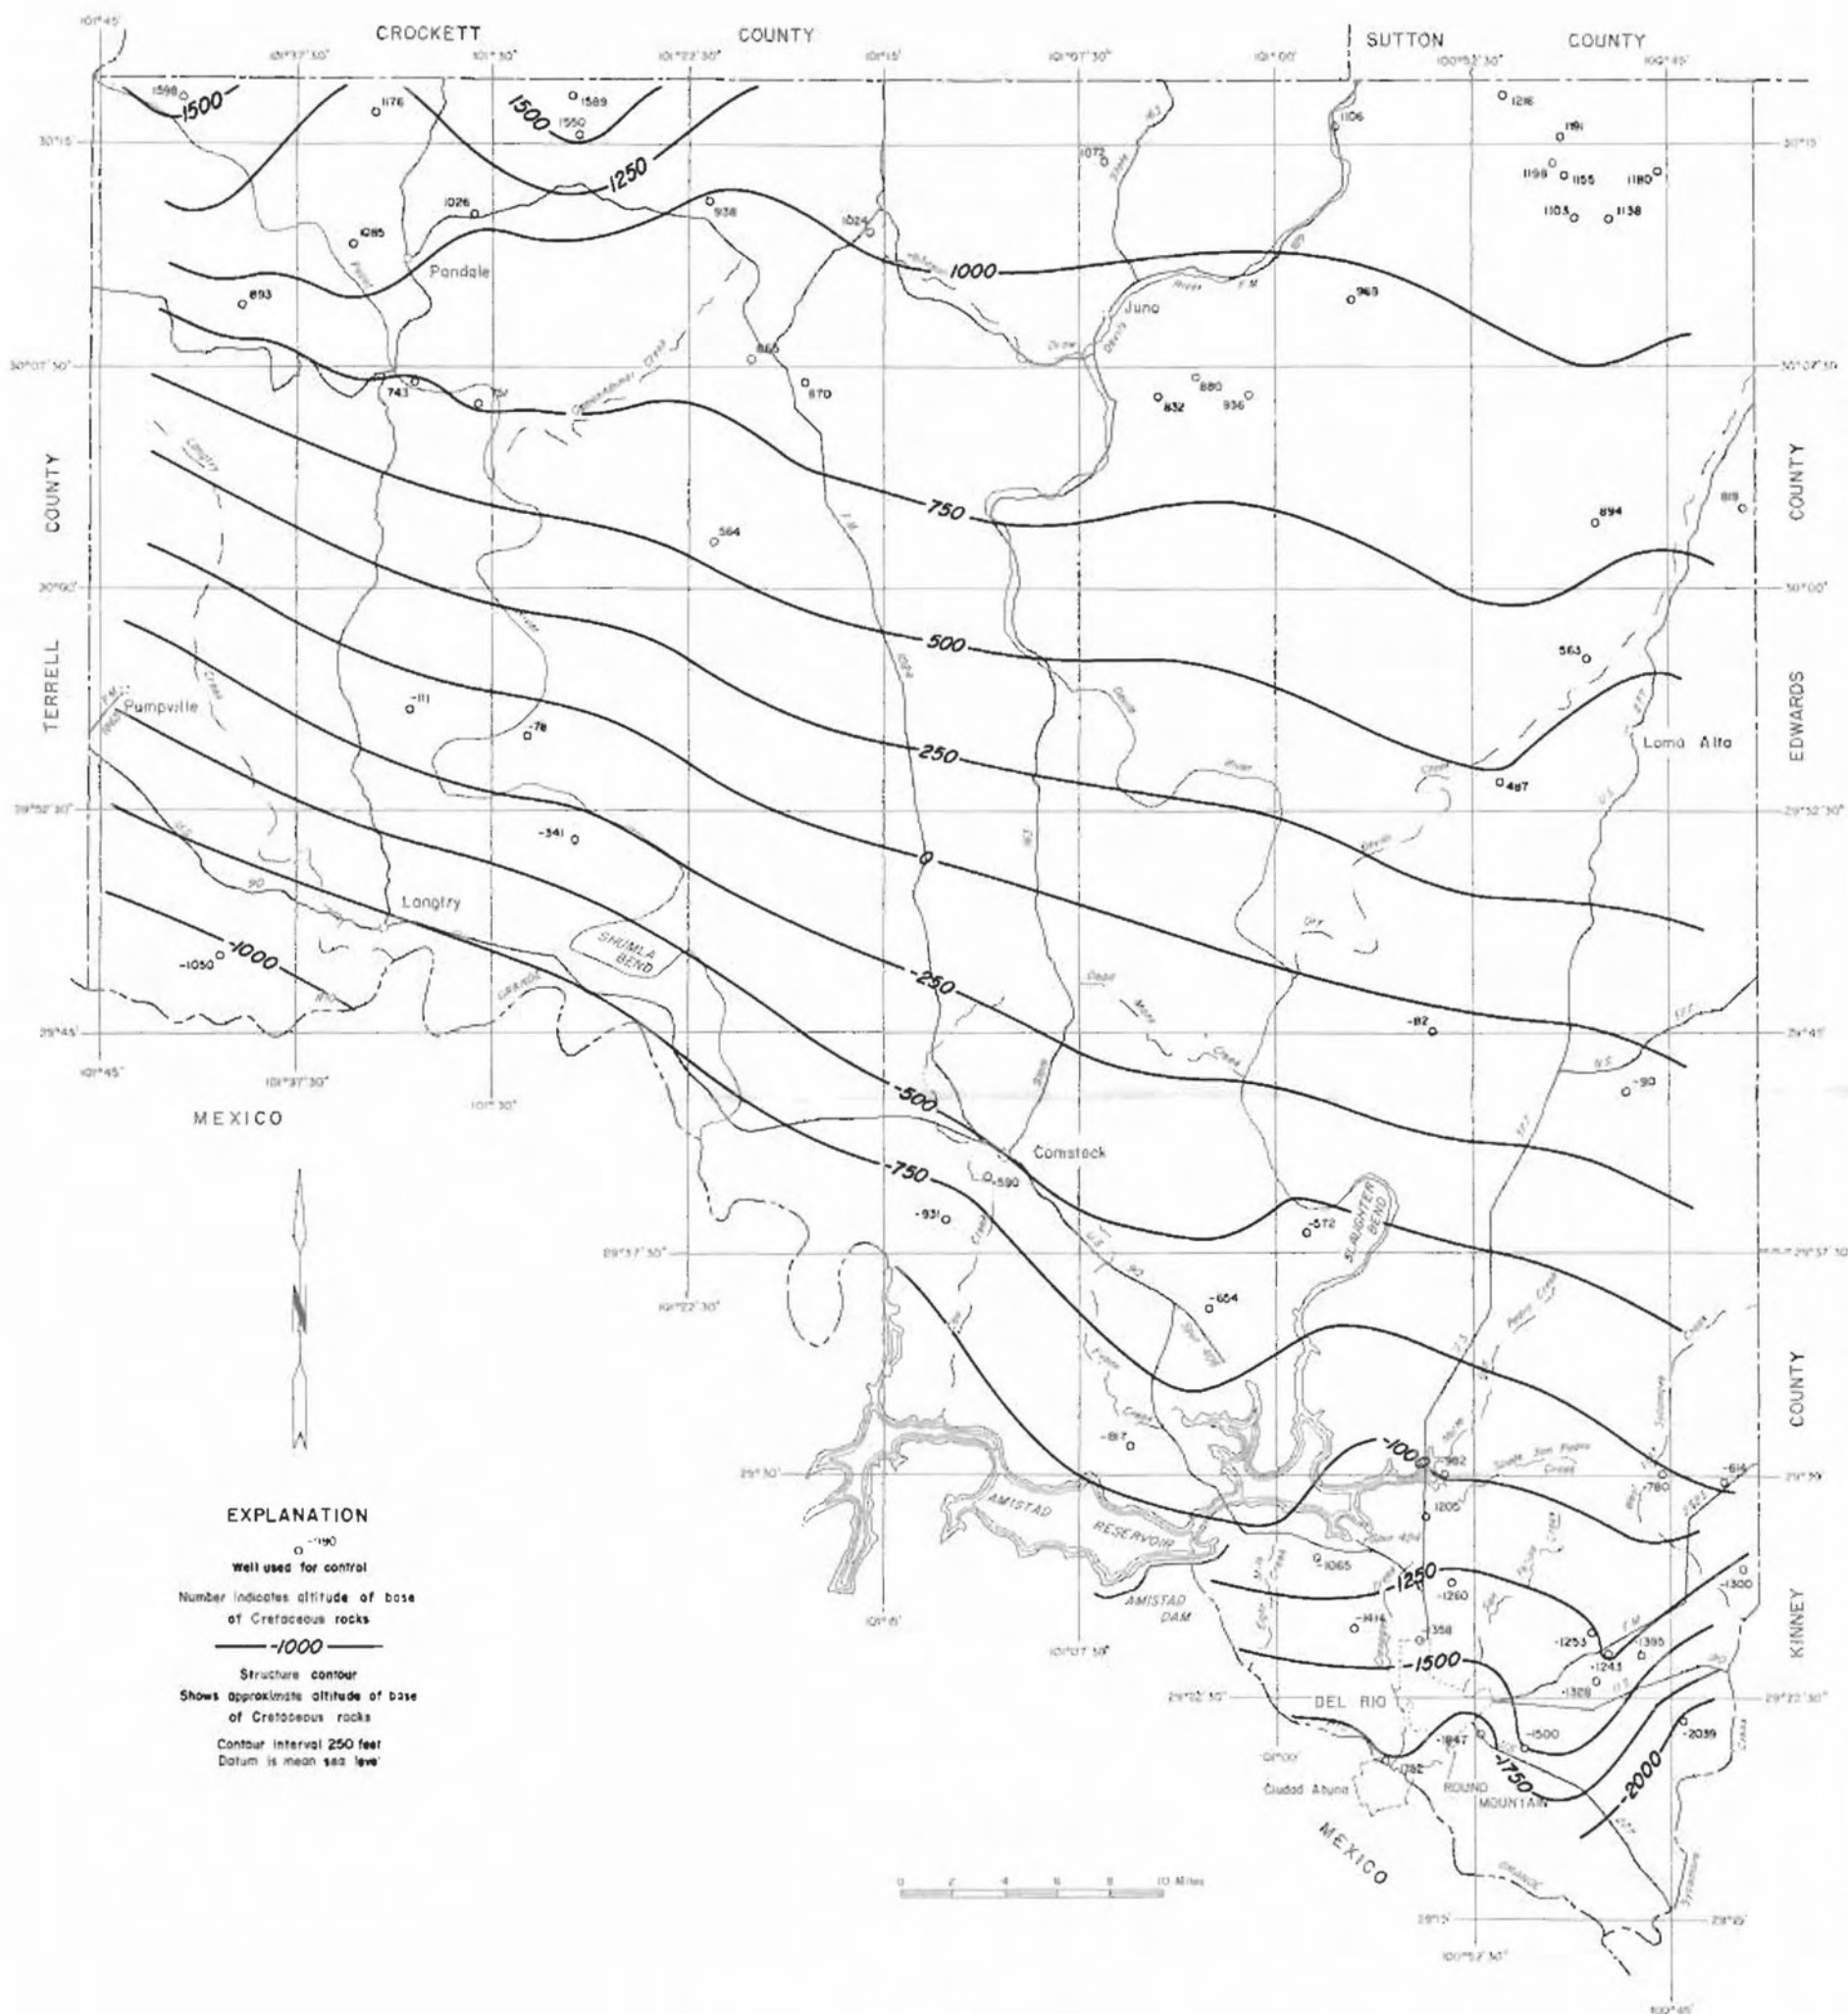

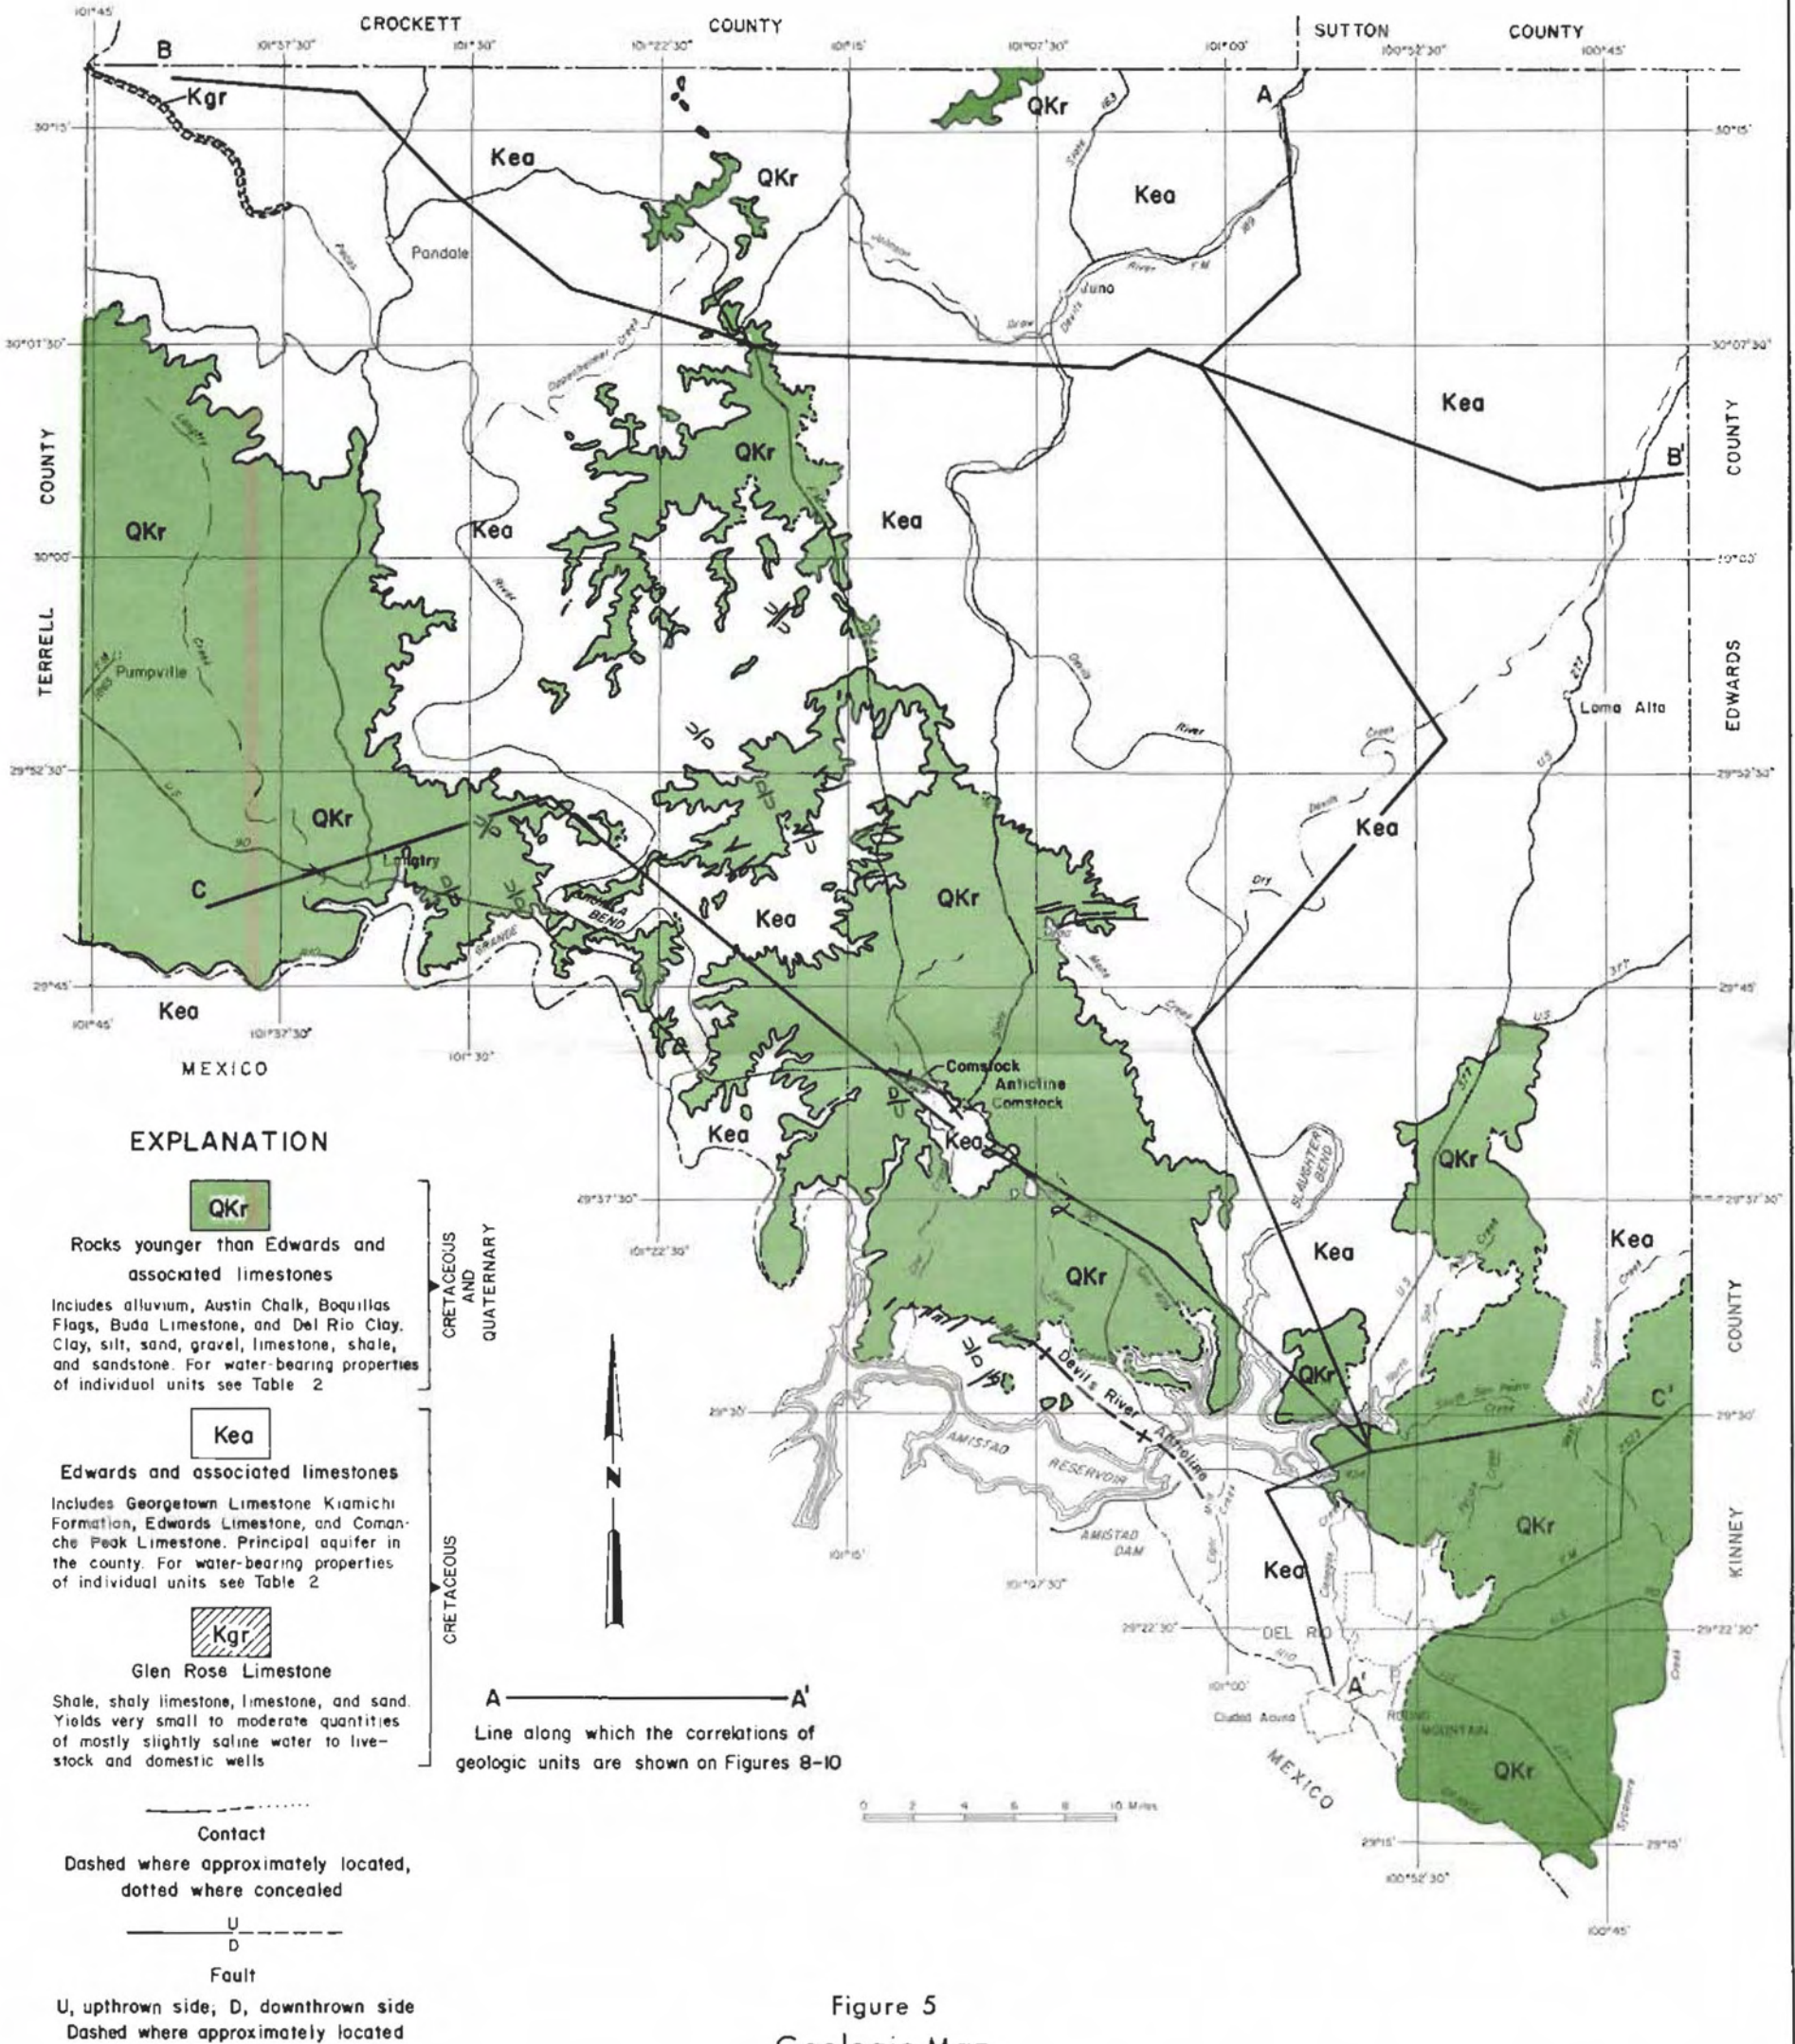

Figure 6
Approximate Altitude of the Base
of the Cretaceous Rocks

Edwards Limestone

Lithologically, the Edwards resembles the Georgetown, and differentiation between these rock units in the field was not made in the northern part of the county. The Edwards Limestone is a light-gray, dense, hard, massive, cherty limestone that is locally dolomitic. In well YR-70-17-701, the thickness of the Edwards is about 300 feet (Figure 8).

The Edwards Limestone is one of the principal aquifers in Val Verde County. Water of good chemical quality from wells tapping this unit is used for irrigation, domestic supply, and livestock in the northern two-thirds of the county. In this area, the Edwards generally is not fully saturated and the water levels are deep. In some areas in the northern quarter and the extreme western part of the county where the Edwards yields only a few gallons per minute to wells, a few wells (such as wells YR-54-55-404, YR-70-02-302, and YR-71-03-101) were drilled into the underlying Glen Rose Limestone to obtain additional water.

Nearly all the wells that tap the Edwards Limestone in the northern two-thirds of the county yield very small to small quantities of water; however, near the Devils River north of Juno, the Edwards Limestone yields large quantities of water to a few irrigation wells. In the southern one-third of the county, some wells tap the Edwards Limestone, but most of the water pumped is from the Georgetown Limestone.

The areas most favorable for drilling large-capacity wells in the Edwards Limestone are near the major streams (such as the area north of Juno), near faults or fracture systems, and in the southern part of the county, where the aquifer is fully saturated.

The chemical quality of water in the Edwards Limestone varies widely within the county, but in general it is suitable for most purposes, although it is somewhat hard. In the southern part of the county, some wells tapping the Edwards Limestone yield slightly saline water.

Kiamichi Formation

The thickness of the Kiamichi Formation ranges from about 50 feet at well YR-71-24-302 at the confluence of Dead Mans Creek and Devils River (Figure 18) to about 283 feet in well YR-70-33-702 near Del Rio (Table 5). This formation is absent or unrecognized north of a line from about the mouth of the Pecos River to the junction of U.S. Highways 277 and 377 (Figure 18). North of this line, the Comanche Peak, Edwards, and Georgetown Limestones are lithologically similar and were described together by Udden (1907, p. 55-60) as the Devils River Limestone. South of this line, the Kiamichi Formation is recognizable as a distinct lithologic unit. It is recognized at the outcrop

in only two places in the county, both of which are in the Devils River Valley. Approximately the uppermost 20 feet of Kiamichi crops out in a small area at the mouth of Dead Mans Creek, and the top 2 or 3 feet are exposed about 1 mile northwest of well YR-70-17-901 in the Slaughter Bend area (Figure 18).

The Kiamichi Formation consists chiefly of dark-brown to dark-gray shaly limestone and dark-gray to black, brittle, calcareous shale that contains some anhydrite, gypsum, and chert in the area east and southeast of Amistad Dam. North and northwest of Amistad Dam, it is a gray to brown, slightly shaly limestone and contains some chert, the unit is distinguishable from the overlying Georgetown principally by its shale content.

Cores from wells YR-70-33-702, YR-71-40-501, and YR-71-40-901 indicate that the Kiamichi contains many fractures and solution openings as well as thick beds of anhydrite and gypsum. Evidence of intraformational collapse was observed in several beds. The collapse probably resulted from the conversion of anhydrite to gypsum and the solution of gypsum by water percolating along fractures.

East and southeast of Amistad Dam, the Kiamichi contains a greater thickness of shale than elsewhere in the county. This shale is nearly impermeable and thus restricts ground-water movement between the overlying Georgetown Limestone and the underlying Edwards Limestone. Differences in ground-water head between these two formations have been observed in wells where the thick beds of shale in the Kiamichi are known to separate them. North and northwest of Amistad Dam, where the Kiamichi Formation is thinner, it is not known to restrict ground-water movement between the overlying Georgetown and underlying Edwards Limestone.

The water-bearing properties of the Kiamichi Formation in Val Verde County are not well known. Wells tapping the overlying Georgetown Limestone usually supply sufficient quantities of water for most uses, and very few wells have been drilled into the Kiamichi. Well YR-70-33-903, however, was plugged back because of mineralized water in the Kiamichi, and a large quantity of slightly saline water was pumped from well YR-70-42-209 from a 2-foot cavity at 710 feet in the Kiamichi.

In general, the Kiamichi Formation contains slightly saline to moderately saline water in the explored areas of Val Verde County. Locally, wells such as well YR-70-33-201 may yield water having a strong odor of hydrogen sulfide gas. Near the northernmost extent of the Kiamichi, the water may be fresh.

Georgetown Limestone

The Georgetown Limestone crops out over much of the southern half of Val Verde County. It is a massive cliff-forming limestone, and many of the deep canyons in the southern part of the county are cut entirely in the Georgetown Limestone.

The Georgetown Limestone is chiefly light- to blue-gray, dense, medium- to massive-bedded limestone containing scattered thin shale stringers. The formation contains pyrite and disseminated chert nodules in the lower part. Near Del Rio, where the uppermost 10 to 20 feet of the formation is exposed, it consists of a soft, marly, very light-gray, very pyritic limestone. This upper unit may be present in the subsurface southeast of Del Rio.

The thickness of the Georgetown at the outcrop was not determined. In the subsurface, the thickness ranges from 400 feet to slightly more than 500 feet (Figures 8, 10).

The Georgetown Limestone is the principal aquifer in the southern part of the county where the Kiamichi separates the Georgetown and the Edwards Limestones (shown on Figure 18). Wells tapping the Georgetown yield very small to large quantities of fresh, hard water used for domestic supply, livestock, industry, and irrigation. Because an adequate supply of water is generally available from the Georgetown, wells seldom are drilled into the underlying formations. In the extreme southeastern part of the county, the slightly to moderately saline water in the underlying Kiamichi generally deters further drilling.

Sinkholes are numerous in the areas where the Georgetown Limestone crops out. Some are shallow, circular depressions, ranging from a few to many feet in diameter; and although they do not have a visible inlet, they do not hold water. These sinkholes have a random areal distribution, and the geologic factors that control their development are not apparent. Others are sinkholes with visible inlets that range in size from 0.1 foot to more than 100 feet in diameter. The sinkholes are roughly circular or elongated in shape and are commonly aligned along faults or joints through part of their length. The known depths range from about 1 foot to more than 260 feet.

The holes or shafts may open up at depth into small, roughly circular rooms or into a series of long, narrow, nearly horizontal passageways along solution-widened faults, joints, or bedding planes. Several levels of solution are evident in some of the caves, and a few of the caves have more than one entrance; however, only one cave could be classified as the labyrinth type, that is, "a complex of many irregular and repeatedly connected passages" (Monroe, 1970, p. K2).

A fault cave near the Rio Grande, between Amistad Dam and Del Rio, was followed for about a mile along the intersection of faults and bedding planes. The size of the passageways ranged from large rooms 10 to 15 feet wide and 5 to 8 feet high to small openings less than 2 feet high and 3 feet wide. In general, the cave level is about 2 feet above the present water level and about 30 feet above water-surface altitude of the Rio Grande.

Numerous solution openings from which springs probably issued were observed along the banks of the Rio Grande and Devils River. Some of the openings are as much as 50 feet above the stream level, but most are less than 30 feet above stream level.

A few of the sinkholes in the county intersect the water table and contain pools of water. Flow, which was very slow, was observed in only one pool.

Several sinkholes, primarily near the intersection of Devils River and San Pedro Creek, have been observed to capture all of the storm runoff in the canyon or draw in which they were located. Only very severe storms could produce enough runoff to pass them. This area is now covered by Amistad Reservoir.

At least two of the sinkholes that could capture large quantities of storm runoff were associated with large collapse or subsidence areas, which are common in the Devils River-San Pedro Creek area. In these collapse areas, solution in the Georgetown Limestone apparently formed large caverns whose ceilings could not support the overlying beds of Georgetown and younger formations. Freeman (1968, p. K22-K24) describes other subsidence areas farther west in the county.

In wells tapping the Georgetown Limestone, water is found in solution-widened openings along faults, fractures, and bedding planes at widely varying levels. The limestone itself is dense and practically impermeable. In much of the outcrop area, water rises in a well bore above the point where it first enters the well.

An example of the wide variation in depths to solution openings is shown by the varying range of levels at which solution openings were found in grouting operations along the axis of Amistad Dam. In one area, highly permeable and apparently interconnected solution-widened fractures or faults could be traced in a series of adjacent holes drilled for injecting grout. The solution openings were found at either progressively higher or lower levels in adjacent holes. Fewer solution openings were found in the lower part of the holes, but those that were found were evidently large, as indicated by the reported large volume of grout pumped into them. This data is restricted to a single line of holes located along a 7-mile line along the axis of Amistad Dam from the Rio Grande to Highway 90 and east on Highway 90 to its intersection with Spur 454

(Figure 18). The holes are 3 inches in diameter, 100 to 300 feet deep, and 2 to 20 feet apart. The geologic conditions encountered during these operations are probably more or less typical of the Georgetown Limestone throughout the outcrop area.

Although there are many openings in the subsurface, the chance of finding a large one in any one hole below the potentiometric surface is not good, as indicated by the very few large-capacity wells and the many very small-capacity wells. In the course of field work, some of the ranchers reported that several borings were drilled before obtaining a well having an adequate capacity. Well YR-70-33-604 reportedly yields a small supply of water from a solution opening at about 500 feet, and well YR-70-33-602 yields a large supply of water from a solution opening between 210 and 230 feet. A solution opening yielding a large supply of water between 460 and 570 feet was reported in well YR-71-23-502 near Comstock. Two nearby wells, YR-71-23-504 and YR-71-23-505, were drilled to depths of about 1,000 feet and neither of them yielded more than 10 gpm.

Del Rio Clay

The Del Rio Clay overlies the Georgetown Limestone in most of the southern part of the county. The type section of the Del Rio Clay is southeast of Del Rio at a conical butte called Loma de la Cruz by Hill and Vaughn in 1898 (Sellards and others, 1932, p. 387). This is probably the hill called Round Mountain on the Del Rio quadrangle map. Freeman (1968, p. K6) reestablished the name Del Rio Clay for this area.

The Del Rio is a dark-blue shale that weathers to yellow-brown. Thin beds of sandy limestone and very fine-grained sandstone or silty sandstone are also present.

The formation, which is thickest in the southeastern part of the county (136 feet in well YR-70-42-208), is missing entirely in the area from west of Shumla Bend into Terrell County (over the Terrell Arch) and north of a line from Shumla Bend to about the confluence of the Dry Devils River with the Devils River (Freeman, 1968, p. K8).

The Del Rio Clay is not known to yield water to wells in Val Verde County.

Buda Limestone

The Buda Limestone, which overlies the Del Rio Clay, crops out extensively in the southern part of the county. In general, it is composed of three parts: The upper and lower parts are light tan or very pale orange, hard, very dense sublithographic or porcelaneous limestone containing small specks of calcite; the middle part is a marly, nodular limestone.

The Buda Limestone ranges in thickness from about 50 feet near the Devils River north of Slaughter Bend and along the Pecos River as far south as Shumla Bend (Freeman, 1968, p. K10) to about 90 feet on the south bank of South San Pedro Creek (West Texas Geological Society, 1959, p. 46).

The Buda Limestone yields very small quantities of fresh water to a few wells in Val Verde and Kinney Counties.

Gulf Series

The Gulf Series in Val Verde County is composed of the Boquillas Flags and the Austin Chalk.

Boquillas Flags

In Val Verde County, the Boquillas Flags is the western equivalent of the Eagle Ford Shale (Sellards and others, 1932, p. 431). The Boquillas rests unconformably on the underlying Buda (Freeman, 1968, p. K10) and crops out over most of the southwestern part of the county. Elsewhere in the county, it occurs occasionally in isolated thin patches capping the higher hills.

The Boquillas is composed chiefly of light- to dark-gray, thin- to medium-bedded, silty, sandy, dense limestone and very thin beds of black, calcareous shale. The range in thickness of the formation was not determined; however, in well YR-71-11-902 the thickness was at least 258 feet.

The Boquillas Flags yields very small quantities of fresh to slightly saline water to a few wells in Val Verde County. The formation has a limited saturated thickness, due chiefly to its high topographic position and to its small areal extent. Its transmissive properties are generally low, and it is therefore an unimportant source of water in Val Verde County.

Austin Chalk

The Austin Chalk crops out in two areas in southwestern Val Verde County. It is exposed extensively in an area of 70 to 90 square miles between Langtry and the Terrell County line and caps the high hills in an area of 15 to 20 square miles about 4 miles north of Comstock and west of State Highway 163. It conformably overlies the Boquillas Flags and may be as thick as 200 feet (Freeman, 1968, p. K14). The Austin Chalk consists primarily of thin- to thick-bedded, hard, light tan to yellow-gray limestone and very thin to thin beds of laminated shaly limestone.

The Austin Chalk is not known to yield fresh water to wells in Val Verde County.

Quaternary System

The alluvium of Pleistocene and Holocene age consists of clay, silt, sand, and gravel and commonly occurs as floodplain deposits along the major streams and some of the major arroyos. Terrace deposits containing gravels derived from rocks far to the west occur on bluffs along the Rio Grande. The maximum observed thickness of alluvium was found in the Rio Grande Valley near Del Rio, where there are about 50 feet of silt, sand, and gravel.

A few shallow wells in the flood-plain deposits yield very small to moderate quantities of fresh water for livestock or domestic use.

GROUND WATER HYDROLOGY

Source and Occurrence

The source of recharge for the water-bearing formations (aquifers) in Val Verde County is precipitation within the county and in adjacent counties. Most of the precipitation is evaporated from the land surface, transpired by plants, or runs off as stream or floodflow. Only a small amount of the precipitation ultimately reaches the water table to become part of the ground water in storage.

Ground water occurs under water-table (unconfined) conditions or artesian (confined) conditions. Under water-table conditions, the water will not rise in wells above the point where it is first encountered; under artesian conditions, the water is confined by relatively impermeable layers and will rise above the base of the upper confining layer. The head that causes the water to rise in the well is maintained by the water in the aquifer in areas of recharge. The head in the artesian aquifer in Val Verde County results from the higher head maintained in the topographically higher areas in the updip extension of the artesian aquifer.

The surface to which the water will rise in wells is called the potentiometric surface. Water-table conditions occur in the Edwards and associated limestones in the northern part of the county and in the alluvial deposits in the county as a whole; artesian conditions generally occur in the Edwards and associated limestones in the southern part of the county.

Recharge, Movement, and Discharge of Ground Water

The study of the recharge, movement, and discharge of ground water in Val Verde County was concerned primarily with the Edwards and associated limestones, the principal aquifer in the area. Recharge to the aquifers in Val Verde County occurs chiefly by

direct infiltration of precipitation and streamflow on the outcrop areas within the county and in adjacent counties. A small amount of recharge occurs locally by vertical seepage along faults and fractures or through semiconfining beds (interformational leakage).

The outcrops contain sinkholes and solution-widened fractures and faults which readily permit infiltration of ground water. The hydrograph of the discharge of San Felipe Springs is compared with the hydrograph of the water levels in well YR-70-42-205 and the graph of precipitation at Del Rio on Figure 11. The rapid rise of the water level in the well and the increased discharge from the spring in response to heavy rainfall are characteristic of the fluctuations of water levels in wells and spring discharge throughout the county. The rise in 1969 was also affected by the filling of Amistad Reservoir.

Ground water moves slowly under the influence of gravity from areas of recharge to areas of discharge. The movement is seldom uniform in direction or velocity. The rate of movement of ground water is a direct function not only of the size of the open spaces and interconnecting passages in rocks but also of the existing hydraulic gradient. Where water is withdrawn by pumping, the local direction of ground-water movement is toward the well from all directions.

Water entering the Edwards and associated limestones moves downward under the force of gravity to the water table or zone of saturation. Regionally, water in the zone of saturation moves down the hydraulic gradient through a system of interconnected openings along faults, joints, and bedding planes towards discharge areas (springs and seeps) along the stream valleys.

The regional south-southwest hydraulic gradient is shown on Figure 12. The hydraulic gradient is at right angles to the water-level contours representing the potentiometric surface; however, locally, water may move nearly parallel to the contours. Bennett and Sayre (1962, p. 82) indicated that in Kinney County ground water moving through solution channels in the Edwards and associated limestones probably moves nearly parallel to the water-level contours.

In Val Verde County, ground water is discharged to the surface by springs and seeps, by evapotranspiration where the water table is near the surface, and by wells. Subsurface discharge occurs mainly by vertical seepage through semiconfining beds or along faults and fractures into other aquifers having a lower hydrostatic head. As an example, during drilling and testing of well YR-71-40-901 it was observed that the water level in the Edwards Limestone was 6 feet higher than the water level in the overlying Georgetown. Subsequently, a liner was set from the surface through the Georgetown and into the Kiamichi Formation to separate the Edwards from the Georgetown so that

Figure 11.—Comparison of Discharge From San Felipe Springs, Water Level in Well YR-70-42-205, and Precipitation at Del Rio

periodic water-level measurements of the two formations could be made in the same well bore. Although the differences in water levels of the two formations were erratic, the altitude of the water level in the Edwards remained higher than that in the Georgetown throughout the period of record (Table 6). In general, the greatest differences occurred during the rising trend resulting from the filling of Amistad Reservoir.

Another well in this area, YR-71-40-501, had a similar difference in water levels. The water level in the Edwards was 4 to 6 feet higher than the water level in the Georgetown. The well was later plugged with cement through the Kiamichi, and the water level returned to the Georgetown level.

The quantity of water discharged by wells is very small compared to that discharged by springs and seeps. The largest of these springs are San Felipe Springs and Goodenough Springs. The flow of the springs during drought periods is sustained primarily by underflow into the county and from storage in the aquifer north and east of the springs. During wet periods, part of the discharge of the springs is from local recharge in nearby sinkholes. Much of this water, however, moves off rapidly and is discharged through springs.

The average annual discharge of San Felipe Springs from 1961 to 1967 was about 57,900 acre-feet (International Boundary and Water Commission, United States and Mexico, 1967, p. 45). The contributing area for San Felipe Springs, about 1,000 square miles, is east and northeast of Del Rio in parts of Val Verde, Kinney, and possibly Edwards Counties. Bennett and Sayre (1962, p. 81) indicate that ground water enters Val Verde County as underflow from northwest of Brackettville in Kinney County. Undoubtedly, much of this underflow is discharged at San Felipe Springs, because no springs of significance exist between San Felipe Springs and Sycamore Creek, the eastern boundary of the county.

The average annual discharge (1930-67) of Goodenough Springs, now covered by Amistad Reservoir, was about 96,000 acre-feet (International Boundary and Water Commission, United States and Mexico, 1967, p. 26). The extent of the contributing area for Goodenough Springs is unknown. It appears feasible that much or all of the sources of these springs are to the north and northeast, in a direction from which the regional ground-water movement in the aquifer is indicated by the contours on Figure 12. However, it is also possible that an unknown quantity of water may be derived from sources to the northwest and west. When

Amistad Reservoir reaches its normal stage of 150 feet over Goodenough Springs, the spring flow may be diverted to other outlets.

Relation Between Ground Water and Streamflow

Direct or storm runoff (flood flow) is water resulting from precipitation and is defined as overland flow that enters a stream. Ground water discharged from the saturated zone through seeps and springs to the stream is commonly referred to as base flow. The base flow of the Devils River and the discharge from Goodenough Springs, San Felipe Springs, Cantu Spring, Eight Mile Spring, McKee Spring, and six measured springs in Mexico are entirely from the Edwards and associated limestones.

The total base-flow contributions from the Edwards and associated limestones to the Rio Grande can be estimated for a particular period of low flow by adding the base flow of the Rio Grande at Fosters Ranch gaging station on the Terrell-Val Verde County line (Figure 18) to the measured base flow of the tributaries and springs.

During periods of low flow, the difference between the flow of the Rio Grande measured at the International Bridge between Del Rio, Texas, and Ciudad Acuna, Coahuila, Mexico, and the above summation is the base flow attributable to unmeasured springs along this reach of the river. Half of this unmeasured spring flow is assumed to enter the river from Val Verde County and half from Mexico. The base flow of the Pecos River in Val Verde County was estimated from a low-flow investigation by the U.S. Geological Survey (Spiers and Hejl, 1970, 13 p.).

The discharge of the rivers and streams in Val Verde County has been measured at stream-gaging stations (Figure 18) or by seepage investigations. Streamflow hydrographs have been plotted, and the base-flow component has been identified by a graphical method where separation of base and floodflow was required. The average annual flow of the springs (base flow of the streams) for the period 1961-67 was then estimated as follows:

	THOUSANDS OF ACRE-FEET PER YEAR
Pecos River	32
Goodenough Springs	89
Devils River	240
Minor springs on the Rio Grande	2
Unmeasured springs on the Rio Grande	81
San Felipe Springs	58
	502

The sum of these flows represents the approximate average annual discharge of ground water from the Edwards and associated limestones during the period 1961-67.

Recharge from rainfall within the county (3,242 square miles) sufficient to supply the above discharge would have to be about 2.9 inches per year or 16 percent of the average annual rainfall in the county. The recharge rate seems to be high in comparison with that occurring in nearby counties where the recharge is roughly equivalent to 1 to 2 inches over the county area. The long-term average recharge for the nearby counties of Edwards, Kerr, Kinney, and Real are 1.3 (Long, 1963, p. J24), 1 (Reeves, 1969, p. 12), 1.4 (Bennett and Sayre, 1962, p. 76), and 2 inches (Long, 1958, p. 21) respectively.

It seems more likely that the ground-water recharge, equivalent to the base flow in Val Verde County, occurs in a basin roughly bounded by a line from the intersection of Lozier Canyon and the Rio Grande north-northwest to Sheffield in Pecos County, east-northeast from Sheffield to Eldorado in Schleicher County, south-southeast from Eldorado to Brackettville in Kinney County, and then back due west to Del Rio (Figure 1). The size of this basin is about 6,500 square miles or 4,160,000 acres. Ground-water recharge in an area this size required to equal the 500,000 acre-feet of base flow in Val Verde County is about 1.5 inches or 9 percent of the estimated average annual precipitation of 16 inches over the 6,500 square miles.

Use of Ground Water

Only small quantities of ground water are pumped from the aquifers in Val Verde County. Most of the water used in the county is obtained from springflow. Nearly all of the water used is from the Edwards and associated limestones.

During 1969, about 1,850 acre-feet or 1.7 mgd (million gallons per day) of ground water was pumped for all purposes. Of this amount, an estimated 1,200 acre-feet (1.1 mgd) was for domestic and livestock use.

The use of ground water for irrigation is declining in the county. In 1958, nearly 2,400 acre-feet (2.1 mgd) was used to irrigate about 2,200 acres; in 1964, nearly 2,200 acre-feet (1.9 mgd) was used to irrigate about 1,300 acres (Gillett and Janca, 1956). By 1969, only about 600 acre-feet (0.5 mgd) was used to irrigate about 300 acres.

In 1969, about 50 acre-feet (0.04 mgd) of ground water was pumped for public supply, mostly for the communities of Comstock, Langtry, and Pumpville. The city of Del Rio obtains its municipal supply from San Felipe Springs; the usage in 1969 was 6,780 acre-feet (6.0 mgd).

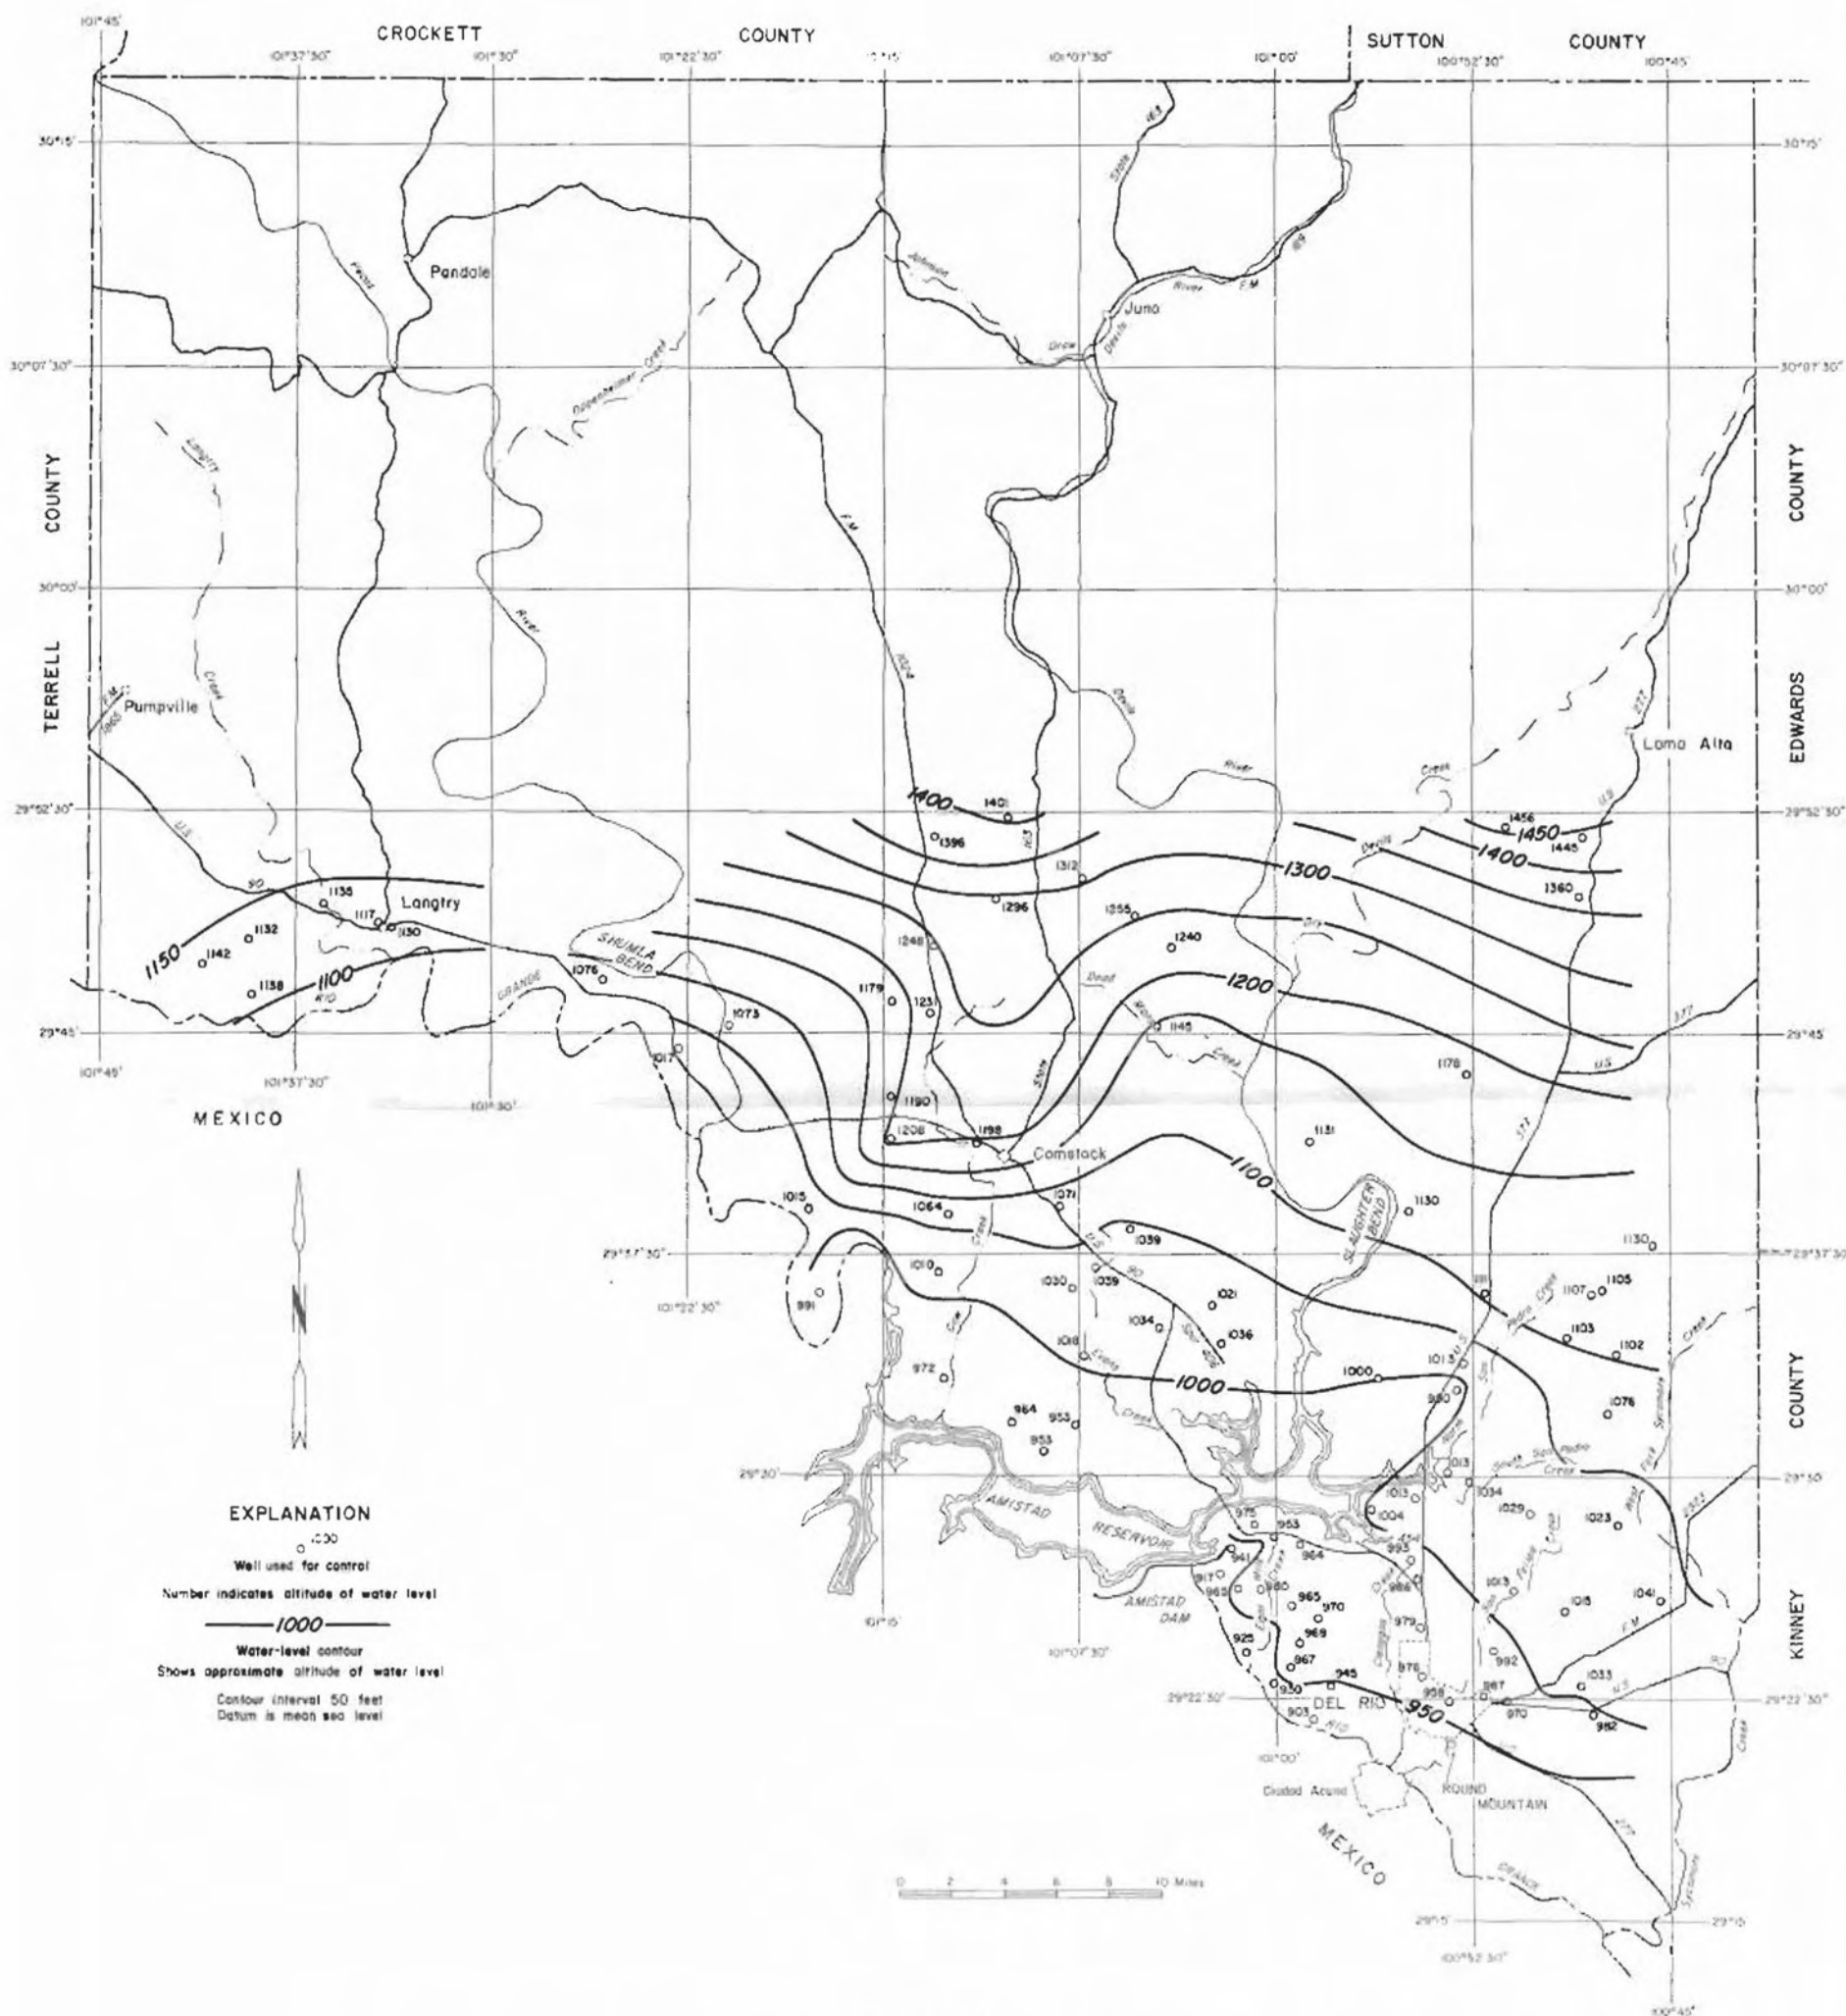

Figure 12
 Approximate Altitudes of Water Levels in Wells Tapping the Edwards
 and Associated Limestones Near Amistad Reservoir, July 1968

Fluctuation of Water Levels

Water levels in wells in Val Verde County fluctuate mainly in response to the relative quantities of recharge to the aquifer and natural discharge from the aquifer. A rise in water levels indicates greater recharge than discharge and more water in storage; whereas a decline in water levels represents greater discharge than recharge and less water in storage.

Records of water levels since 1954 are available from the Texas Water Development Board for wells near Juno in the northern part of the county. Records of several intermittent water-level measurements made by the U.S. Geological Survey in three wells in the southeastern part of the county are available for two wells since 1937 and for the other since 1954. Water-level records of a large number of wells in a large area above and below Amistad Reservoir are available

from the International Boundary and Water Commission since 1964. Water-level records of selected wells are shown in Table 6.

Hydrographs of representative wells tapping the Edwards and associated limestones are compared with precipitation at Del Rio on Figure 13. Wells YR-54-56-501 and YR-55-49-102 are in the northern part of the county and well YR-70-41-304 is in the southern part of the county (Figure 18). The water levels in the wells usually are highest during periods of greatest rainfall and lowest during periods of drought. These hydrographs plus the hydrograph for well YR-70-42-205 (Figure 11) show in general that water levels in the aquifer were a few feet lower in late 1969 than they were during the wet years of 1958 and 1959. However, the hydrographs show very little net change in water levels throughout the period of record.

Figure 13.—Water Levels in Wells Tapping the Edwards and Associated Limestones and Annual Precipitation at Del Rio

Records of water-level fluctuations in wells tapping the alluvium, Buda Limestone, and Glen Rose Limestone are too meager for comparative purposes. The greatest fluctuation of water levels in the county occurred in the vicinity of Amistad Reservoir.

Impoundment of water in Amistad Reservoir began in July 1968, and water levels in wells tapping the Edwards and associated limestones near the reservoir began to rise almost immediately. Figure 12 shows the altitude of water levels in wells in the area prior to the

start of impoundment, and Figure 14 shows the altitude of water levels in the same wells about one year later. Figure 15 shows the net changes of water level in wells near the reservoir from about July 1968 to about July 1969. Water levels in wells nearest the reservoir have risen more than 100 feet, and levels in wells farther away have risen proportionately less. The decrease in rate of rise of water levels in the observation wells after four months (Figure 16) probably is due largely to the slower rise in reservoir stage that occurred when the surface of the reservoir spread out above the relatively narrow stream channel of the Rio Grande and the Devils River.

The areal extent of affected water levels in wells due to impoundment behind Amistad Dam probably will continue to spread until a relatively stable gradient of ground-water flow toward the lake is established. This will happen some time after a stabilized lake level has been effected. The extent to which a stable lake influences aquifer head may become significant to future ground-water development. Water levels in existing wells in many areas will be higher; and although new wells may have to be drilled to similar depths, the aquifer head available for drawdown will be greater.

As the aquifer head in the vicinity of the reservoir rises, new spring outlets at higher elevations probably will result. The flow of many of these springs will remain within the watershed of the reservoir; however, it is possible that new spring outlets may result in areas outside the reservoir watershed, in which case the ground-water contributions to the reservoir area will be decreased. The discharge of these new springs undoubtedly will enter the river downstream from the dam, and the overall ground-water contributions to the Rio Grande in Val Verde County will not be changed significantly.

Yields of Wells

Yields of wells in Val Verde County range from a few gallons per minute to more than 1,000 gpm. This results from the variability of the capacity of the fissure-type openings to yield and store water. A well bore may intersect large openings along fissures below the water table, and usually the drawdown in a pumped well tapping those openings is small and water-level recovery rapid after pumping stops. Another well bore may intersect relatively small openings in the rock, and even a windmill that pumps only 2 to 3 gallons per minute may draw the water level down a substantial amount in a short time. Return to static level after pumping stops may take many hours. Most of the wells inventoried in the county were pumped by windmills; nevertheless, the drawdown in many of these wells is large compared to the low rate of pumping. The yields and specific capacities for some of the large-capacity wells in the county are given in the following table:

WELL NUMBER	YIELD (GPM)	SPECIFIC CAPACITY (GPM PER FT)	HOURS PUMPED
YR-70-33-101	150	7.4	7
201	205	1.0	2½
502	300	34.5	1½
602	300	10.0	3
903	2,010	18.4	4
42-205	330	24.5	48
208	350	4.4	48
209	475	12.8	48
71-40-302	210	2.5	25
303	172	.8	8

The specific capacity of a well is the ratio of the discharge (gpm) to the drawdown (feet) of water level during a given time interval. It varies with the transmissivity of the aquifer and gives a general index of the capability of the aquifer to yield water. It is not a constant because it gradually decreases with length of pumping time.

The specific capacity of wells in aquifers having large openings may also decrease with increasing discharge because of turbulent flow in the aquifer near the well. Various factors, such as well construction, development, and the size of the well also affect the specific capacity. Properly constructed wells, which have minimal friction losses in the well bore, have higher specific capacities than improperly constructed wells, other factors being equal.

The specific capacities for the wells listed in the foregoing table range from less than 1 to more than 30, which is not unusual for wells tapping a limestone aquifer. Well YR-70-30-601 was pumped during a test at 314 gpm with no measurable drawdown. The drawdown in well YR-71-23-502 was for all practical purposes unmeasurable while the well was pumping 163 gpm.

Well Construction

Most of the wells in Val Verde County are drilled entirely in limestone and, because there is little or no danger of caving, most are not cased. Commonly, 3 to 10 feet of 6- to 8-inch diameter casing is set at the surface to prevent undesirable seepage from the surface or to keep rocks from entering the hole. The wells that penetrate the Del Rio Clay or one of the overlying formations may have casing set through the clay to prevent caving, which occurs in uncased wells especially during the infrequent periods of heavy rainfall. In many of these wells, however, only the top few feet are cased. Most wells are pumped by windmills or small-capacity pumps.

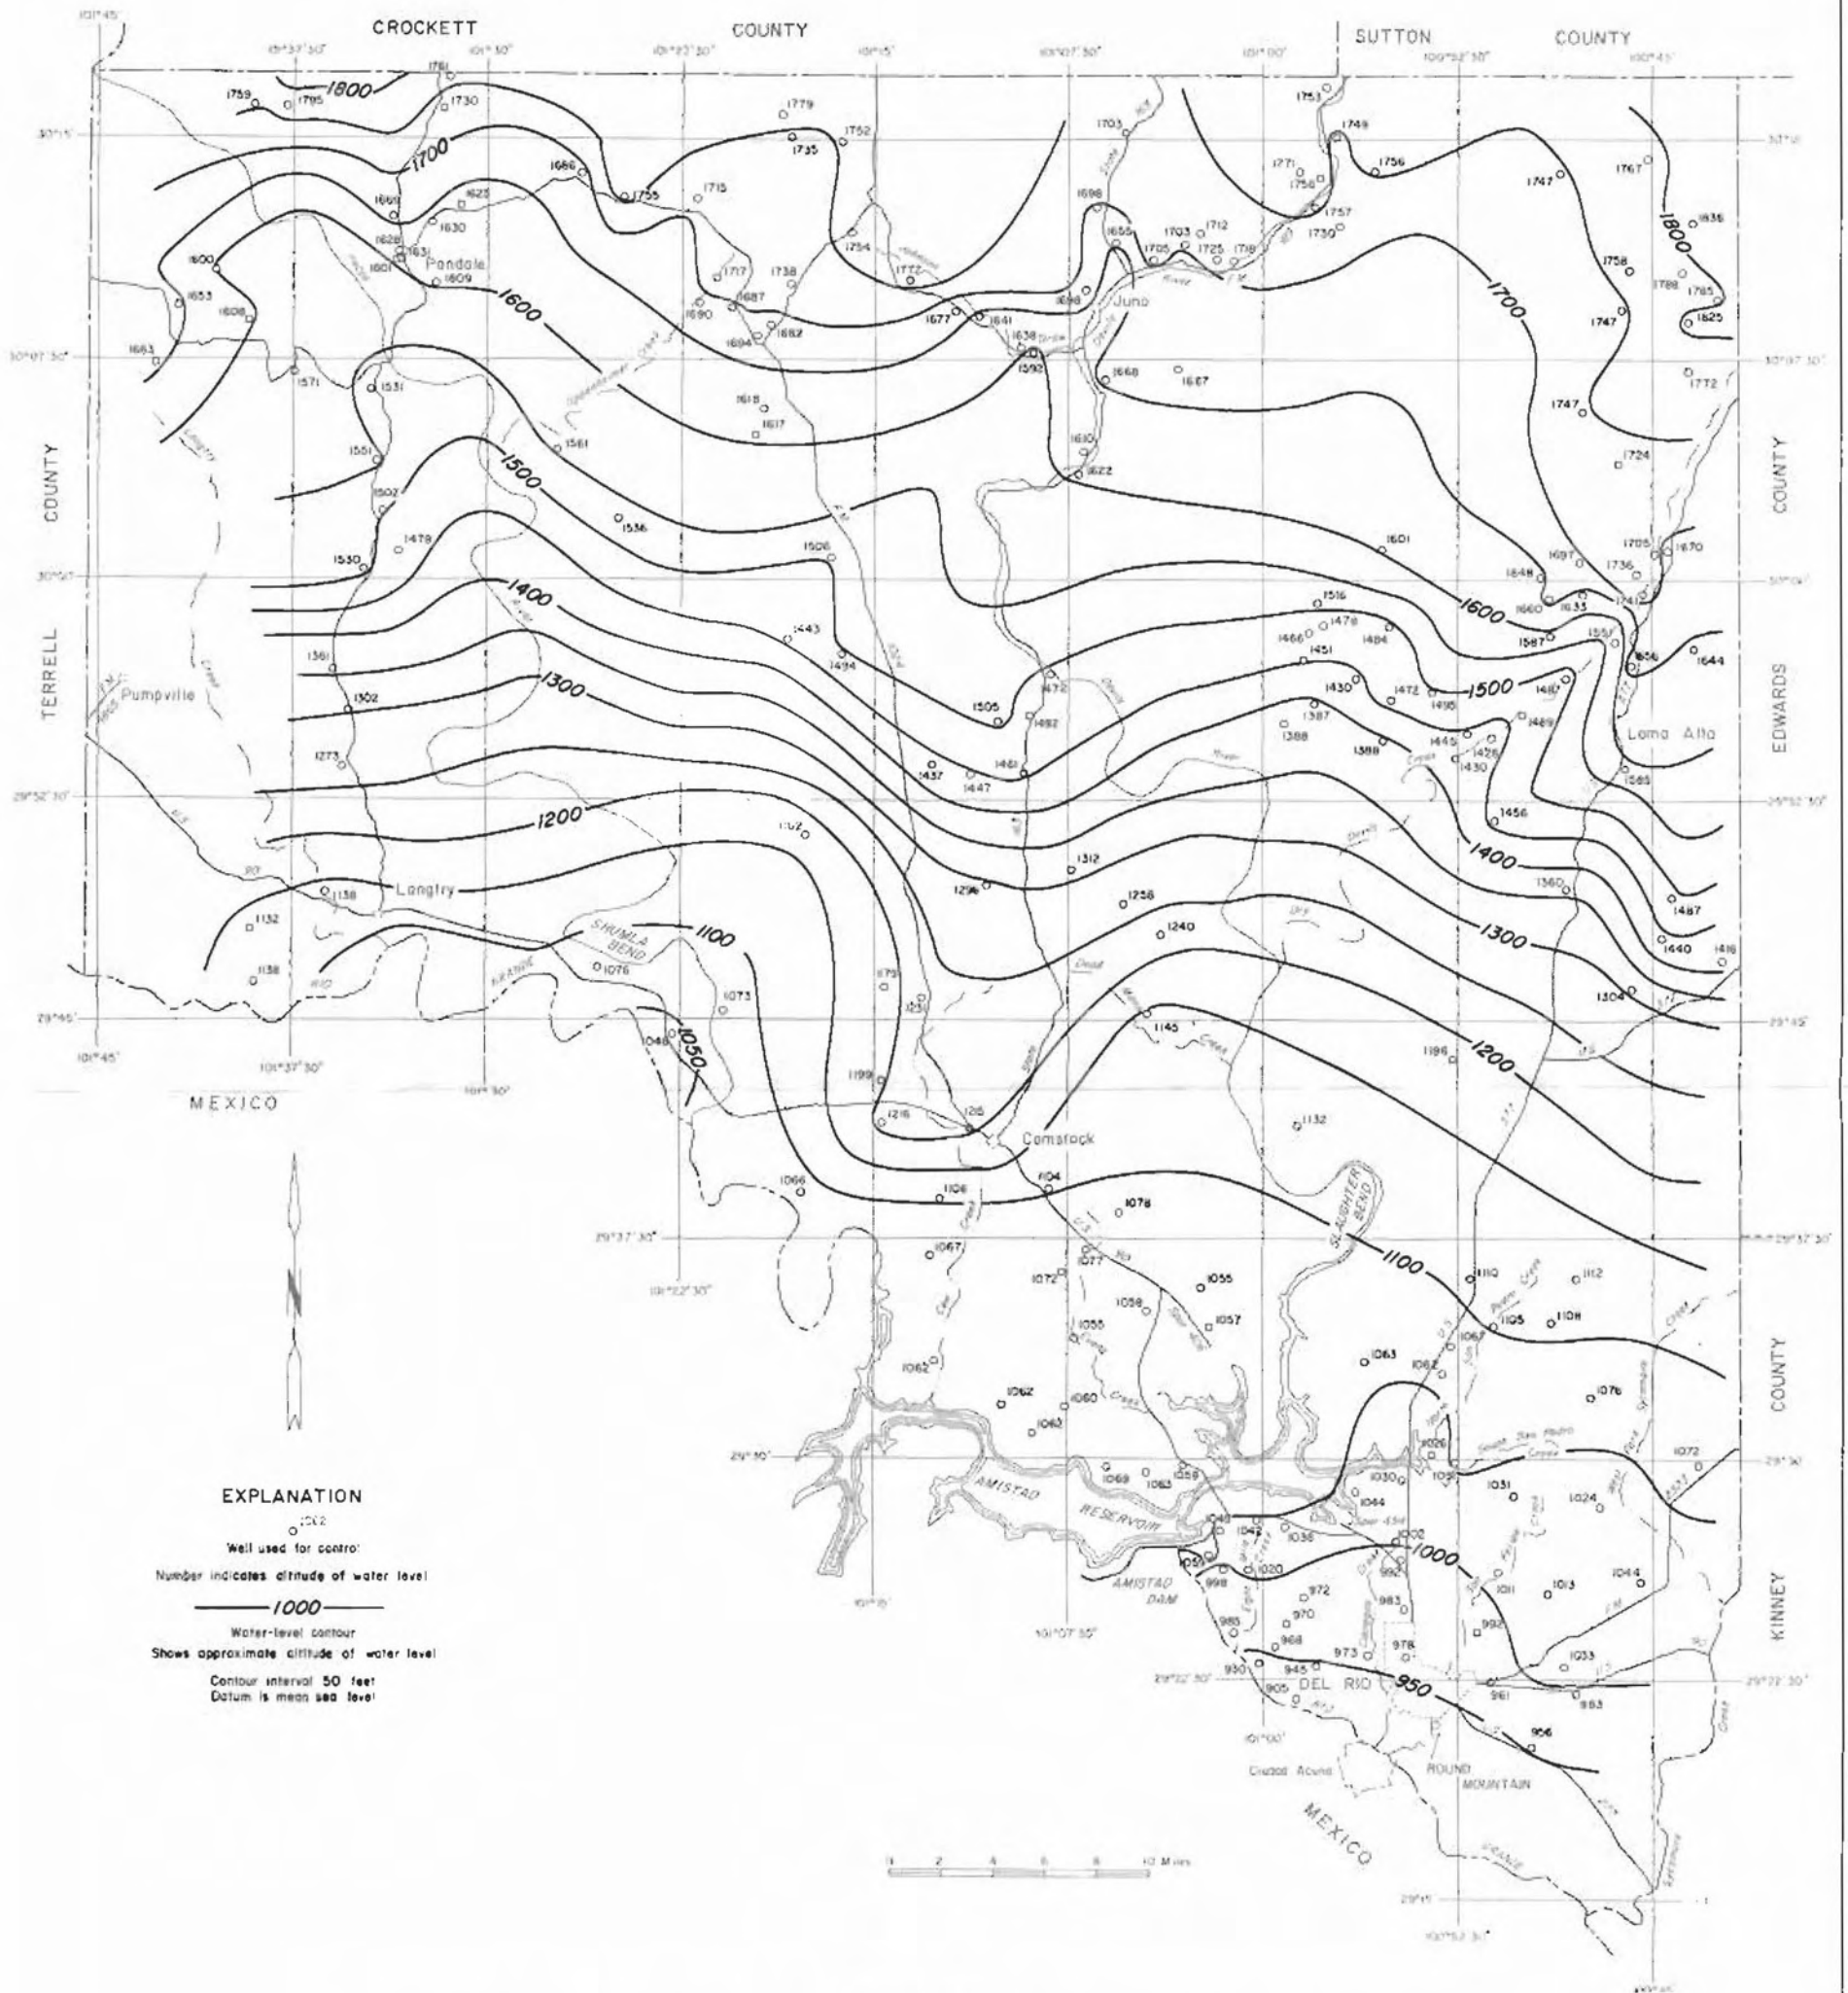

Figure 14
 Approximate Altitudes of Water Levels in Wells Tapping the Edwards
 and Associated Limestones Near Amistad Reservoir, July 1969

Figure 15

Approximate Net Changes of Water Levels in Wells Tapping the Edwards and Associated Limestones Due to Water Impoundment in Amistad Reservoir From July 1968 to July 1969

Figure 16.—Comparison of the Altitude of the Water Surface of Amistad Reservoir and the Altitude of Water Levels in Nearby Wells, 1966-69

A few large-capacity wells, principally for municipal supply or irrigation, are constructed in a

manner similar to the domestic wells, except that larger casing is set. The casing is usually set entirely through the weathered zone, but a slotted liner may be used to protect against caving at depth. The wells are equipped with turbine pumps powered by butane-gas engines.

Hydrochloric acid is frequently used to increase the yield of wells completed in limestone or calcareous sandstone aquifers. The acid dissolves calcium carbonate which clogs the pores or the fissures in the rocks, thereby increasing the effective diameter of the well and reducing the drawdown. This type of well development commonly significantly increases the yield of a well. Well YR-70-33-903 was acidized with 10,000 gallons of 15 percent hydrochloric acid. This resulted in an increase in the specific capacity from 23 gpm per foot of drawdown to 69 gpm per foot of drawdown; the well was pumped at about 200 gpm. Later the well pumped more than 300 gpm with no appreciable drawdown.

QUALITY OF GROUND WATER

Chemical Quality of Ground Water

The dissolved minerals in ground water are derived from the rocks and soil through which the water passes. Precipitation is normally relatively free of mineral content; as water makes its way through soil, it picks up minerals and becomes charged with additional carbon dioxide, which greatly increases its capacity to dissolve minerals in the rocks. Therefore, the chemical character of the water reflects generally the mineral composition of the soil and rocks through which the water moves. Water temperature and the duration of time that the water is in contact with the rocks also affect the degree of mineralization of the water.

The chemical analyses of 310 water samples from 207 wells and 17 springs are given in Table 7. The dissolved-solids, sulfate, and chloride content of the water from wells and springs are shown on Figure 17. A line above a well or spring number on Figure 18 indicates that a chemical analysis is given in Table 7.

The approximate boundary between fresh and slightly saline water in the Georgetown Limestone in the southern part of the county is shown by a line on Figure 17. The down-dip limit of occurrence of fresh water in the Edwards Limestone is not known, but it is believed to be north of this line. The increase in dissolved solids south of the line probably results from poor circulation of ground water.

The suitability of any water supply depends upon its intended use and various standards of water quality have been developed for most categories of water use. Water-quality problems involving bacterial content and physical characteristics frequently can be handled economically; however, the removal of certain undesirable minerals may be difficult and expensive.

Table 3.—Source and Significance of Dissolved-Mineral Constituents and Properties of Water

CONSTITUENT OR PROPERTY	SOURCE OR CAUSE	SIGNIFICANCE
Silica (SiO ₂)	Dissolved from practically all rocks and soils, commonly less than 30 mg/l. High concentrations, as much as 100 mg/l, generally occur in highly alkaline waters.	Forms hard scale in pipes and boilers. Carried over in steam of high pressure boilers to form deposits on blades of turbines. Inhibits deterioration of zeolite-type water softeners.
Iron (Fe)	Dissolved from practically all rocks and soils. May also be derived from iron pipes, pumps, and other equipment. More than 1 or 2 mg/l of iron in surface waters generally indicates acid wastes from mine drainage or other sources.	On exposure to air, iron in ground water oxidizes to reddish-brown precipitate. More than about 0.3 mg/l stains laundry and utensils reddish-brown. Objectionable for food processing, textile processing, beverages, ice manufacture, brewing, and other processes. U.S. Public Health Service (1962) drinking-water standards state that iron should not exceed 0.3 mg/l. Larger quantities cause unpleasant taste and favor growth of iron bacteria.
Calcium (Ca) and magnesium (Mg)	Dissolved from practically all soils and rocks, but especially from limestone, dolomite, and gypsum. Calcium and magnesium are found in large quantities in some brines. Magnesium is present in large quantities in sea water.	Cause most of the hardness and scale-forming properties of water; soap consuming (see hardness). Waters low in calcium and magnesium desired in electroplating, tanning, dyeing, and in textile manufacturing.
Sodium (Na) and potassium (K)	Dissolved from practically all rocks and soils. Found also in ancient brines, sea water, industrial brines, and sewage.	Large amounts, in combination with chloride, give a salty taste. Moderate quantities have little effect on the usefulness of water for most purposes. Sodium salts may cause foaming in steam boilers and a high sodium content may limit the use of water for irrigation.
Bicarbonate (HCO ₃) and carbonate (CO ₃)	Action of carbon dioxide in water on carbonate rocks such as limestone and dolomite.	Bicarbonate and carbonate produce alkalinity. Bicarbonates of calcium and magnesium decompose in steam boilers and hot water facilities to form scale and release corrosive carbon dioxide gas. In combination with calcium and magnesium, cause carbonate hardness.
Sulfate (SO ₄)	Dissolved from rocks and soils containing gypsum, iron sulfides, and other sulfur compounds. Commonly present in mine waters and in some industrial wastes.	Sulfate in water containing calcium forms hard scale in steam boilers. In large amounts, sulfate in combination with other ions gives bitter taste to water. Some calcium sulfate is considered beneficial in the brewing process. U.S. Public Health Service (1962) drinking-water standards recommend that the sulfate content should not exceed 250 mg/l.
Chloride (Cl)	Dissolved from rocks and soils. Present in sewage and found in large amounts in ancient brines, sea water, and industrial brines.	In large amounts in combination with sodium, gives salty taste to drinking water. In large quantities, increases the corrosiveness of water. U.S. Public Health Service (1962) drinking-water standards recommend that the chloride content should not exceed 250 mg/l.
Fluoride (F)	Dissolved in small to minute quantities from most rocks and soils. Added to many waters by fluoridation of municipal supplies.	Fluoride in drinking water reduces the incidence of tooth decay when the water is consumed during the period of enamel calcification. However, it may cause mottling of the teeth, depending on the concentration of fluoride, the age of the child, amount of drinking water consumed, and susceptibility of the individual. (Maier, 1950)
Nitrate (NO ₃)	Decaying organic matter, sewage, fertilizers, and nitrates in soil.	Concentration much greater than the local average may suggest pollution. U.S. Public Health Service (1962) drinking-water standards suggest a limit of 45 mg/l. Waters of high nitrate content have been reported to be the cause of methemoglobinemia (an often fatal disease in infants) and therefore should not be used in infant feeding. Nitrate has been shown to be helpful in reducing inter-crystalline cracking of boiler steel. It encourages growth of algae and other organisms which produce undesirable tastes and odors.
Dissolved solids	Chiefly mineral constituents dissolved from rocks and soils. Includes some water of crystallization.	U.S. Public Health Service (1962) drinking-water standards recommend that waters containing more than 500 mg/l dissolved solids not be used if other less mineralized supplies are available. Waters containing more than 1000 mg/l dissolved solids are unsuitable for many purposes.
Hardness as CaCO ₃	In most waters nearly all the hardness is due to calcium and magnesium. All the metallic cations other than the alkali metals also cause hardness.	Consumes soap before a lather will form. Deposits soap curd on bathtubs. Hard water forms scale in boilers, water heaters, and pipes. Hardness equivalent to the bicarbonate and carbonate is called carbonate hardness. Any hardness in excess of this is called non-carbonate hardness. Waters of hardness as much as 60 ppm are considered soft; 61 to 120 mg/l, moderately hard; 121 to 180 mg/l, hard; more than 180 mg/l, very hard.
Specific conductance (micromhos at 25°C)	Mineral content of the water.	Indicates degree of mineralization. Specific conductance is a measure of the capacity of the water to conduct an electric current. Varies with concentration and degree of ionization of the constituents.
Hydrogen ion concentration (pH)	Acids, acid-generating salts, and free carbon dioxide lower the pH. Carbonates, bicarbonates, hydroxides, and phosphates, silicates, and borates raise the pH.	A pH of 7.0 indicates neutrality of a solution. Values higher than 7.0 denote increasing alkalinity; values lower than 7.0 indicate increasing acidity. pH is a measure of the activity of the hydrogen ions. Corrosiveness of water generally increases with decreasing pH. However, excessively alkaline waters may also attack metals.

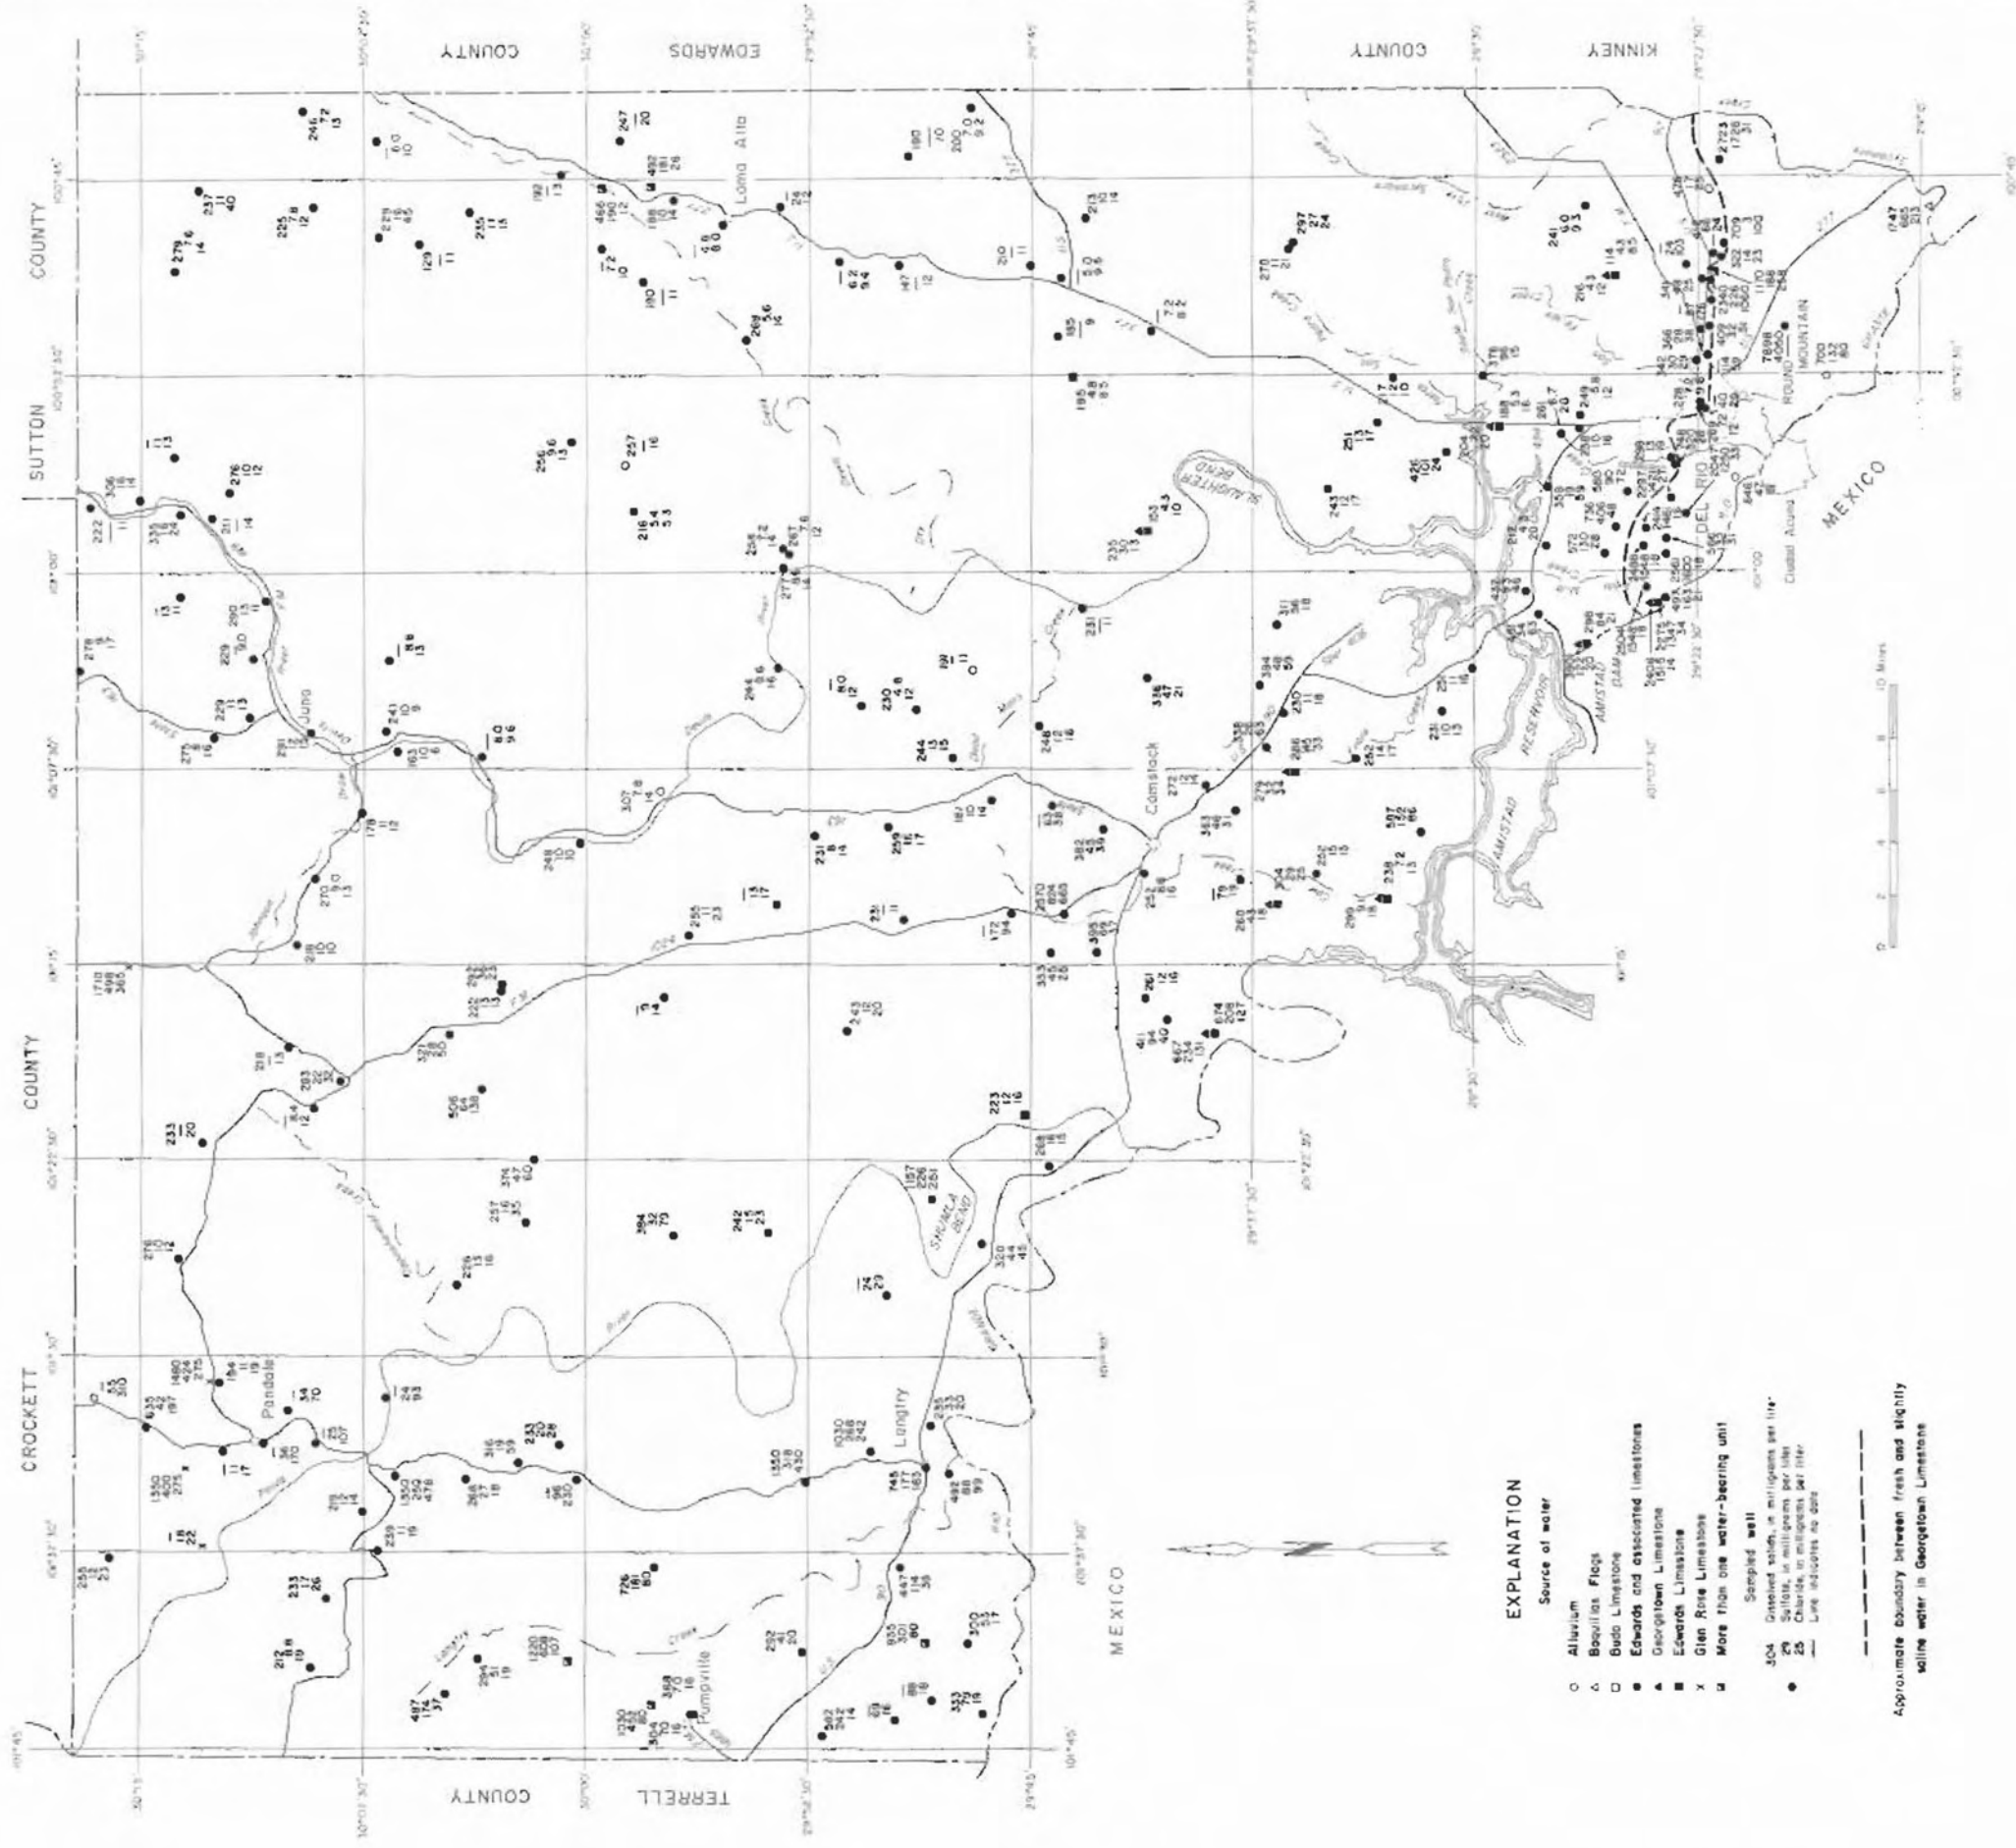

Figure 17
Chemical Quality of Ground Water

For many purposes, the dissolved-solids content places a major limitation on the use of water. A general classification of water, based on dissolved-solids content is as follows (Winslow and Kister, 1956, p. 5):

<u>CLASSIFICATION</u>	<u>DISSOLVED-SOLIDS CONTENT (MILLIGRAMS PER LITER) ↓</u>
Fresh	Less than 1,000
Slightly saline	1,000 to 3,000
Moderately saline	3,000 to 10,000
Very saline	10,000 to 35,000
Brine	More than 35,000

↓ Milligrams per liter (mg/l) is considered equivalent to parts per million (ppm) for water containing less than 7,000 mg/l dissolved solids.

The U.S. Public Health Service establishes standards to control the quality of drinking water to be used on common carriers engaged in interstate commerce. The standards are designed to protect the traveling public and are commonly used to evaluate public water supplies. According to these standards, chemical constituents should not be present in a water supply in excess of the listed concentrations except where other more suitable supplies are not available. Some of the standards adopted by the U.S. Public Health Service (1962, p. 7-8) are as follows:

<u>SUBSTANCE</u>	<u>CONCENTRATION (MILLIGRAMS PER LITER)</u>
Chloride (Cl)	250
Fluoride (F)	.8 *
Iron (Fe)	.3
Manganese (Mn)	.05
Nitrate (NO ₃)	45
Sulfate (SO ₄)	250
Dissolved solids	500

* Upper limit for Val Verde County based on a 39-year average annual maximum daily air temperature of 80.4 °F at Del Rio. The optimum concentration is 0.7 mg/l.

Table 3 shows the source and significance of the major dissolved-mineral constituents and other properties of natural waters (Doll and others, 1963).

Water having a chloride content exceeding 250 mg/l may have a salty taste. The chloride content exceeded 250 mg/l in samples from 11 wells of a total number of 309 samples taken from 223 wells and springs. Water with a high chloride content was primarily obtained from wells in the western part of the county. Such water is not characteristic of any one part of the county or of any one aquifer; but in general, samples

from wells tapping the Glen Rose Limestone and the Edwards and associated limestones in the western part of the county had the highest concentration of chloride.

The upper limit of fluoride concentration for a given community depends on climatic conditions because the amount of water (and consequently the amount of fluoride) consumed is influenced principally by air temperature. The presence of fluoride in water in Val Verde County in average concentrations greater than 1.4 mg/l would constitute grounds for rejection of the supply (U.S. Public Health Service, 1962, p. 8).

A fluoride concentration of 0.7 mg/l in drinking water may reduce the incidence of tooth decay, especially in children, when the water is used during the period of enamel calcification. However, fluoride in excessive concentrations may cause mottling of the teeth (Maier, 1950, p. 1120-1132). The fluoride content in samples collected from 122 wells and springs in the county ranged from 0.1 to 6.2 mg/l. It exceeded 0.7 mg/l in 50 wells and 1.4 mg/l in 32 wells. High fluoride content is found primarily in samples from wells tapping the Edwards and associated limestones and the Glen Rose Limestone in the western part of the county.

The use of water containing iron in excess of 0.3 mg/l and manganese in excess of 0.05 mg/l may cause reddish-brown or dark gray stains on clothes, plumbing fixtures, and utensils. In 30 samples (three from the same well), the iron content ranged from 0 to 12 mg/l and exceeded 0.3 mg/l in 12 wells. The samples having a high iron content were from wells tapping the Glen Rose Limestone and Edwards and associated limestones in the northern and western parts of the county; however, near Amistad Dam, the iron content locally exceeds 0.3 mg/l. High iron concentrations usually can be reduced by aeration and filtration. Only one of three analyses for manganese showed a concentration greater than 0.05 mg/l, the standard of the U.S. Public Health Service, and it was 0.23 mg/l.

Concentrations of nitrate in excess of 45 mg/l in water used for infant feeding have been related to the incidence of infant cyanosis (methemoglobinemia or "blue baby" disease), a reduction of the oxygen content in the blood constituting a form of asphyxia (Maxcy, 1950, p. 271). High concentrations of nitrate may be an indication of pollution from organic matter. The nitrate content in 233 determinations from 191 wells and springs exceeded 45 mg/l in only one well. The highest nitrate concentration was 58 mg/l from well YR-70-50-301, completed in the Boquillas Flats, and the next highest concentration (41 mg/l) was from well YR-70-41-601, completed in alluvium.

Water containing sulfate in excess of 250 mg/l may produce a laxative effect. The sulfate, as determined in 307 samples, ranged from 3 to 4,050 mg/l. Of the 221 determinations tabulated in Table 7 (not more than one per well), the sulfate exceeded the established limit of

250 mg/l in 24 wells. Nearly all of the samples from wells tapping the Glen Rose Limestone contained sulfate in excess of 250 mg/l. Most of the samples from the Edwards and associated limestones containing more than 250 mg/l of sulfate were from wells south of the dashed line on Figure 17.

The dissolved-solids content of 251 water samples ranged from 114 to 7,898 mg/l. Of the 198 determinations tabulated in Table 7 (not more than one per well or spring), the dissolved-solids content was less than 500 mg/l in 160 samples, between 500 and 1,000 mg/l in 16 samples, and more than 1,000 mg/l in 22 samples.

Calcium and magnesium are the principal dissolved constituents that cause hardness of water in Val Verde County. Hard water increases soap consumption and forms scale in hot water heaters, water pipes, and teakettles. Commonly accepted standards and classifications of water hardness are shown in the following table:

HARDNESS RANGE		CLASSIFICATION
MILLIGRAMS PER LITER	GRAINS PER GALLON	
60 or less	3.5 or less	Soft
61 to 120	3.6 to 7.0	Moderately hard
121 to 180	7.1 to 10.5	Hard
More than 180	More than 10.5	Very hard

The water in Val Verde County is generally very hard. The hardness indicated by analyses of 297 samples ranged from 91 to 1,942 mg/l and was less than 180 mg/l in only 23 of the samples from 220 wells and springs tabulated in Table 7.

The quality of ground water from the Edwards and associated limestones is generally satisfactory for irrigation in Val Verde County. Water unsuitable for irrigation, as defined by the classification of the U.S. Salinity Laboratory (1954, p. 69-82), was obtained from one well, YR-70-42-401, in the southeastern part of the county. This classification is based primarily on the salinity hazard as measured by the specific conductance of the water and on the sodium hazard as measured by the SAR (sodium adsorption ratio). The specific conductance was 8,780 micromhos per centimeter, and the SAR was 18.

Wilcox (1955) reported that water generally may be used for supplementary irrigation if the specific conductance of the water is less than 2,250 micromhos per centimeter at 25°C and its SAR is less than 14. The specific conductance of 218 samples of water from 167 wells and springs in the Edwards and associated limestones ranged from 224 to 8,780 micromhos per

centimeter, exceeding 2,250 in samples from only 13 wells.

The SAR was more than 14 in only one sample (well YR-70-42-401), which also had the highest specific conductance. The specific conductance of samples from four wells penetrating the Glen Rose Limestone ranged from 536 to 2,750 micromhos per centimeter. The SAR of three of the samples ranged from 9.9 to 10.

The RSC (residual sodium carbonate) is also used to assess the quality of water for irrigation. Excessive RSC will cause the water to be alkaline, and the organic material in the soil will tend to dissolve. The soil may become a grayish-black, and the land areas affected are referred to as "black alkali." Wilcox (1955, p. 11) states that laboratory and field studies have resulted in the conclusion that water containing more than 2.5 me/l (milliequivalents per liter) RSC is not suitable for irrigation. Water containing from 1.25 to 2.5 me/l is marginal, and water containing less than 1.25 me/l RSC probably is suitable. However, the successful use of marginal water for irrigation might be made possible by proper irrigation practices and use of soil amendments. Furthermore, the degree of leaching will modify the permissible limit to some extent (Wilcox and others, 1954, p. 265).

The RSC in 107 samples ranged from 0.00 to 1.43 me/l. In the samples from 103 wells and springs, the RSC was 0.00 me/l. The two samples having an RSC value were from wells tapping the Glen Rose Limestone (0.43 and 1.43 me/l).

Water is not suitable for irrigation if it has an excessive boron content. Wilcox (1955, p. 11) indicates that the maximum permissible boron concentration for irrigating sensitive crops is 1.0 mg/l, for semitolerant crops 2.0 mg/l, and for tolerant crops 3.0 mg/l. Boron concentrations are not a problem in Val Verde County. All 23 samples which were analyzed for boron showed concentrations of less than 0.5 mg/l.

Another factor used in assessing the suitability of water for drinking purposes is the presence of pesticides. During the investigation, water samples collected from three wells (YR-70-41-203, YR-71-03-301, and YR-71-23-101) and one spring (YR-40-41-301) were analyzed for pesticides (nine insecticides and three herbicides). The concentrations of all pesticides were less than 0.005 µg/l, (micrograms per liter) in the water samples collected from the wells and were not tabulated. The sample collected from the spring contained 0.01 µg/l of DDT [1, 1, 1-trichloro-2, 2-bis (p-chlorophenyl) ethane]. However, the concentration of DDT in a second water sample collected from the spring was less than 0.005 µg/l, which is the lowest detectable concentration of pesticides. Concentrations of pesticides permissible in public water supplies, adapted from Water quality criteria—report of the National Technical Advisory Committee to the Secretary of the Interior:

Federal Water Pollution Control Administration, 1968—are given in the following table:

INSECTICIDE (MICROGRAMS/LITER)		HERBICIDE (MICROGRAMS/LITER)	
Aldrin	17	2, 4-D plus	
DDT	42	2, 4, 5-T plus	100
Dieldrin	17	Silvex	
Endrin	1		
Heptachlor	18		
Heptachlor epoxide	18		
Lindane	56		

Changes in Quality of Ground Water

No pollution of ground water from salt-water disposal pits or from inadequately cased oil or gas wells in Val Verde County was observed or reported during this study. Very little oilfield brine has been produced in conjunction with oil in Val Verde County.

Crude oil production in 1968 was 20,843 barrels, and accumulative recorded production through 1968 was 35,385 barrels. The amount of brine produced in conjunction with the crude oil was small, and there is probably no immediate danger to the ground-water supply from salt-water disposal.

According to salt-water disposal inventory (Texas Water Commission and Texas Water Pollution Control Board, 1963), 730 barrels, or about 0.1 acre-foot, of salt water was produced from one well in the Vinegarone Field (Figure 18) in the extreme northeast part of the county. The salt water was disposed of in an open pit. In 1968, according to the files of the Railroad Commission, about 8,900 barrels or 1.1 acre-feet of salt water was disposed of in open pits.

Although the Texas Railroad Commission issued a "no-pit" order effective January 1, 1969, the disposal of salt water into surface pits is still permitted in Val Verde County. Exceptions to this rule are occasionally granted to operators in areas where, in the Commission's opinion, the possibility of salt water contaminating ground water or surface water is negligible because of impermeable surface rocks or very little salt-water production.

In recent years, the Texas Water Development Board has made recommendations to oil and gas operators of the depths to which water-bearing formations are to be protected; and the Oil and Gas Division of the Railroad Commission of Texas is responsible for the protection of water-bearing formations. Although the amount of casing required for oil and gas wells in the Vinegarone Field is not specified

by the Railroad Commission, the surface casing of the wells is adequate to protect the fresh water in the field. In general, the wells are cased and cemented to a depth of about 20 feet below the base of the Cretaceous rocks.

The disposal of salt water into unlined surface pits is a possible source of pollution of the ground water because the Edwards and associated limestones underlie the surface in most of the county. However, unless large-scale production of oil and salt water, coupled with poor salt-water disposal practices, takes place within the county or in the recharge area north and northeast of Val Verde County, there is little danger of widespread ground-water pollution in the county due to oil production activities. In the event that large-scale oil and brine production does develop in the areas mentioned, a systematic sampling for chemical analysis of ground water from wells located on the periphery of the disposal areas will aid in detecting and locating any widespread pollution.

Some evidence of pollution of ground water by salt water exists in the vicinity of Pandale (Figure 17). A comparison of the chemical analyses of water samples collected from wells YR-54-52-503 and YR-54-52-601 and springs YR-54-52-801 and YR-54-60-302 in this area shows an increase in chloride content from the 1939 samples to the 1968-69 samples (Table 7). The chloride content of the samples from well YR-54-52-201 decreased from 400 mg/l in 1961 to 256 mg/l in 1968, and to 197 mg/l in 1969, indicating that perhaps salt water pollution in the late 1950's and early 1960's was of greater intensity than it is today.

This pollution probably spread as underflow from Crockett County where, according to Iglehart (1967, p. 40), the salt water produced with oil usually was stored in unlined surface pits in the early days of oil production. However, in some instances, the salt water was discharged into ephemeral creeks, into open crevices, or into sinkholes in the outcrop of the Edwards and associated limestones. Salt-water disposal by any of these methods in limestone terrain is almost certain to reach the ground-water body either by direct infiltration along faults, fissures, or joints in areas where sinkholes or crevices in the limestone exist, or by infiltration of the overflow from the pits during periods of intense rainfall.

The slightly saline water in wells YR-54-60-201, YR-71-04-801, YR-71-12-201, and YR-71-13-601, which tap the Edwards and associated limestones near the Pecos River, is probably the result of local recharge of slightly saline water from the river. Although an overall gain in base flow of the river in Val Verde County was evident during the low-flow investigation by Spiers and Hejl (1970, p. 12), some of the losses in base flow between individual measuring sites are believed to be caused by diversion of water along solution-widened fractures to wells near the river.

One well was apparently polluted by infiltration of highly-mineralized water from an unknown source. The owner of well YR-71-23-101 reported that the quality of water in the well had deteriorated in June 1968. The sulfate and chloride content of a water sample collected from the well in August 1968 was 824 and 665 mg/l, respectively. The sulfate and chloride content in a water sample from the same well had decreased to 355 and 185 mg/l by August 1969, indicating that the mineralized water probably was being diluted and moving down dip.

AVAILABILITY OF GROUND WATER FOR FUTURE DEVELOPMENT

The ground-water resources of Val Verde County are relatively undeveloped. The availability of water for future development depends on recharge and the capacity of the aquifer to transmit and store water. The aquifer properties will not change with time, but the recharge will vary with the amount of rainfall and the stage of Amistad Reservoir.

Whether or not the pre-Cretaceous rocks and the Glen Rose Limestone have much water suitable for development is unknown. In some areas, the quality of water in these aquifers is poor, and the transmissive and

storage properties are not favorable for extensive or large-scale development. However, too little is known about them to adequately evaluate their future potential. Except in those areas where no other water is available, little exploration in these aquifers is expected in Val Verde County. The development of Amistad Reservoir will insure adequate surface water and relatively shallow ground-water supplies to a large area in southern Val Verde County, and few developers will be looking to deeper aquifers for future supplies.

The Edwards and associated limestones are the principal aquifer in the county. The limestones are capable of furnishing much larger quantities of water than are being withdrawn at the present (1969). The basic problem will be finding specific sites favorable for development of large-capacity wells. Prior to the impoundment of water behind Amistad Dam (July 1968) base-flow records of the Rio Grande and the Pecos and Devils Rivers and the discharge records of Goodenough and San Felipe Springs indicated that approximately 500,000 acre-feet of water per year had been naturally discharged. Therefore, this amount of water could be developed from the Edwards and associated limestones with little net change in the water level. A substantial increase in ground-water usage, however, would result in a decrease in springflow.

Table 4.--Records of Wells and Springs in Val Verde and Kinney Counties

All wells are drilled unless otherwise notes in remarks column.

Water level : Reported water levels are given in feet; measured water levels are given in feet and tenths.
 Method of lift and type of power : C, centrifugal; E, electric; G, gasoline, butane, or diesel engine; N, none; P, piston; S, submersible; T, turbine; W, windmill. Number indicates horsepower.
 Use of water : D, domestic; Ind, industrial; Irr, irrigation; P, public supply; S, livestock; U, unused.
 Water-bearing unit : KQ, Pleistocene, and Holocene alluvial deposits; Kbo, Boquillas Flags; Kbu, Buda Limestone; Kea, Edwards and associated limestone; Kgr, Glenn Rose Limestone; Ke, Ellenburger Group.

Table 3.—Chemical Analyses of Water from Wells and Springs in Val Verde and Kinney Counties

Analyses given are in milligrams per liter, except percent sodium, sodium absorption ratio, residual sodium carbonate, specific conductance, and pH.
Water-bearing unit: 80, Hartsogene, and Holocene alluvial deposits; 81a, Ruppelias Flints; 81b, Beds limestones, Kies, Edwards and associated (limestones), Kgr., Chis. Near Llanoesteno.

WELL	SOURCE OF WATER IN DEPTH OF WELL (FEET)	DATE OF COLLECTION	WATER-BEARING UNIT	SILICA (SiO ₂) (PPM)	IRON (Fe) (PPM)	CALCIUM (Ca) (PPM)	MAGNESIUM (Mg) (PPM)	SODIUM AND POTASSIUM		NICKEL-NICKELATE (Ni) (PPM)	SULFATE (SO ₄) (PPM)	CHLORIDE (Cl) (PPM)	FLUORIDE (F) (PPM)	STRONTIUM (Sr) (PPM)	MOLYBDENUM (Mo) (PPM)	BARIUM (Ba) (PPM)	SODIUM ABSORPTION RATIO	SODIUM CARBONATE (Na ₂ CO ₃) (PPM)	SPECIFIC CONDUCTANCE AT 25° C.

1) Where one value is present, sodium and potassium are calculated as sodium (Na).
 2) Salts (SO₄) less than 10 milligrams per liter.
 3) Nitrate (NO₃) less than 20 milligrams per liter.
 4) Analyzed by U.S. Salinity Laboratory.
 5) Residue at 180°.
 6) Iron in solution.
 7) Sample collected at this depth was from Edwards Limestone.
 8) Sample collected at this depth was from Georgetown Limestone.
 9) Sample collected at this depth was from Comanchi Formation.
 10) Determination for calcium (Ca) is 0.00.
 11) Determination for magnesium (Mg) is 0.03.
 12) Determination for manganese (Mn) is 0.00.
 13) Determination for manganese (Mn) is 0.00.
 14) Determination for manganese (Mn) is 0.23.
